THE TUBERCULO-OPSONIC INDEX IN ITS RELATION TO THE TEMPERATURE CURVE IN ACTIVE TUBERCULOSIS AND ITS VALUE IN DIAGNOSIS IN SUSPECTED OR ARRESTED CASES.

By HERBERT MAXON KING, M.D.,

LOOMIS SANATORIUM,

LIBERTY, N. Y.

The following observations and experiments on the relation of the body temperature to the opsonic index and the diagnostic value of the opsonic index in cases of (*a*) suspected or completely arrested tuberculosis, and (*b*) mixed infection in advanced progressive tuberculosis were made at the Loomis Sanatorium during the autumn and winter of 1908-09. They are selected from a large number of similar observations and experiments as being most typically illustrative.

They were suggested, very largely, by experiments of A. C. Inman made at Brompton Hospital Sanatorium (Frimley) during the winter of 1907-08,[1] and by the work of Latham and Inman on a nearly related subject during the following summer.[2] The ordinary technique and usual methods of securing the blood, washing the leucocytes, preparing the slides, staining, etc., were employed. At least 100 phagocytes were counted in every instance. Inman's suggestion of having an assistant mark each specimen in cypher, to avoid possible bias, was followed and the mean of two "normals" was used as unity in each case. Moreover, all of the laboratory work including the counting was done by one laboratory assistant (Mr. George Sheridan) who has been throughout unprejudiced as to results. Thus while no argument is made for the precise accuracy of opsonic index determinations, these results may be taken as correspondingly significant.

The relation of body temperature to the opsonic index.—One of the most characteristic phenomena of active tuberculosis is the succession of temperature elevations alternating with temperature depressions. While it has long been recognized that this phenomenon indicates a succession of spontaneous autoinoculations which, if not controlled, lead to irreparable mischief, the credit is due to Sir A. E. Wright and his colleagues for having been the first to demonstrate this fact and the rationale of the treatment by rest as the most effective method of combating this condition. It was fair to suppose that if the rise in temperature and the attendant constitutional depression manifest once or twice daily in acute tuberculosis were dependent upon spontaneous autoinoculations from the focus of disease that there would appear corresponding changes in the opsonic index—that is to say, that alternating negative and positive phases corresponding inversely to the temperature rise and fall would be demonstrable, and that the temperature curve and the index curve plotted upon the same chart would produce the so-called "diamond curve" of Inman. Such has indeed been shown to be the case. Not only in spontaneous autoinoculations but also in artificially produced auto-inoculations. The interesting charts presented at the recent International Congress on Tuberculosis in Washington by Doctor Latham and Doctor Inman were most convincing in this particular, especially in view of the severe conditions under which the experiments were conducted. As before stated, every effort was made to maintain the same rigid conditions in carrying out the following experiments, which were made as a preliminary to those that follow, and with the object of confirming or discrediting as the case might be, the views of Inman and Latham.

For the past two years it has been found that in our laboratory the normal variations in the opsonic index seldom exceed 1.15 above and 0.85 below unity. Nevertheless, because a somewhat greater variation is sometimes recorded in normal sera, it was thought safer to adopt the limits of normal as prescribed by Bullock and to count only such indices as exceeded 1.2 above and 0.8 below unity as abnormal, and this plan has been followed throughout. All temperatures are rectal. They were taken and recorded by the nurse in charge of the patient. At the same time that the temperatures were taken specimens of the blood were obtained. The slides were prepared and stained on the same day and were labeled in cypher by another assistant. In no instance did the laboratory assistant know the blood he was counting, nor was he aware of the temperatures of the patients. Subsequently the index was plotted by reference to the cypher and then the temperature curve superimposed.

Case I is that of a woman with an advanced active lesion involving three lobes with considerable cavity. Blood and temperature were taken at intervals of two hours from noon of one day to noon of the day following. Examination of the chart (Figure 1) shows a fairly typical "diamond curve"—*i. e.* approximately the index is low when the temperature is high and vice versa. Once during the twenty-four hours the index was recorded above and three times below the extreme normal limits, while from four o'clock in the afternoon until six in the morning it was for the most part well within these limits. It will thus be seen that had opsonic index determinations been made only between these hours instead of extending the observation over the whole period an erroneous impression of the actual reaction going on would have been gained in this instance.

Case II is that of the same patient two months later. In this instance the procedure differs from that in Case I in that the observations extend over portions of three days—viz., from noon to 11:00 P.M. the first day, from 2:00 to 7:00 P.M. the following day, and from 10:00 A.M. to 7:00 P.M

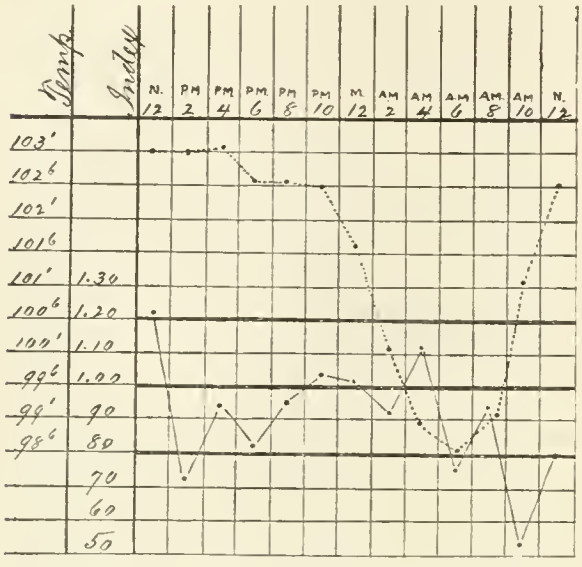

Fig. 1.—Relation of the tuberculo-opsonic index (continuous line) to body temperature (dotted line), producing the "diamond curve."

on the third day. It will also be noticed that the intervals vary between successive observations on a single day from two to six hours. Otherwise, the conditions were the same. From the chart (Figure 2) it will be remarked that in this instance the "diamond curve" is almost perfectly produced. In fact, it is by far the most typical in our collection of these studies. Such a chart scarcely leaves room

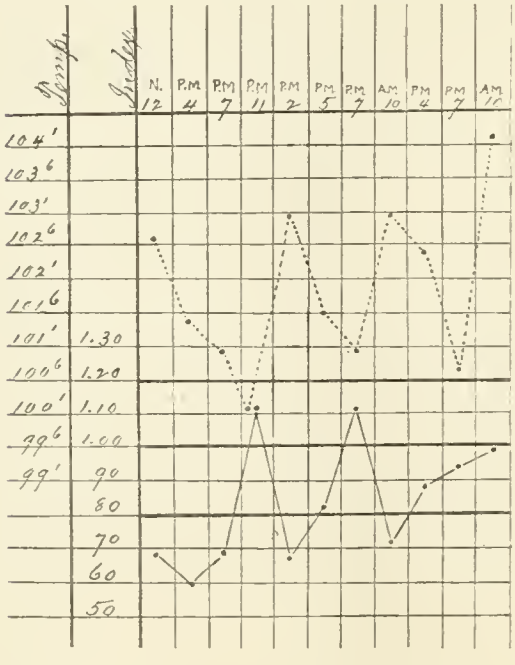

Fig. 2.—Same case as Fig. 1, also showing "diamond curve."

for doubt as to the nature of the spontaneous autoinoculations occurring in this case.

Case III is that of a woman with an involvement of four lobes and cavity, the present acute phase following a considerable period of quiescence. Blood and temperature were in this case taken at intervals of two hours from noon of one day to that of the next. The "diamond curve" is here less typical. At no time during the twenty-four hours did the index register above normal limits, yet a study of the chart (Figure 3) will show in a general way the inverse relationship between the tem-

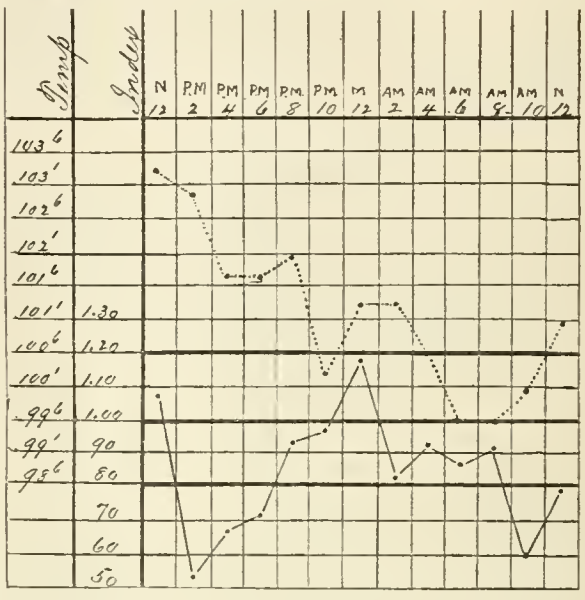

Fig. 3.—Relation of the tuberculo-opsonic index (continuous line) to body temperature (dotted line), producing less typical "diamond curve."

perature and the opsonic index. The two rather extremely low indices in this chart are noteworthy falling as they do at appropriate phases of the temperature curve.

Case IV is that of a woman with an involvement of five lobes, but without cavity. Four observations were taken on the first day in this case at intervals of three hours and three on the day

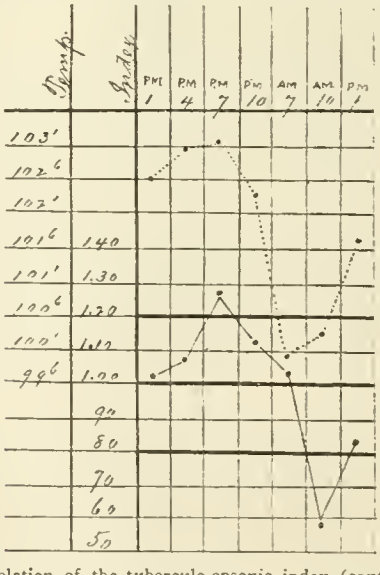

Fig. 4.—Relation of the tuberculo-opsonic index (continuous line) to body temperature (dotted line), showing "delayed" specific autoinoculation.

following at the same intervals. This chart (Figure 4) is given because of the atypical character of the "diamond." It seems to show, nevertheless, a definite corelationship between the temperature and index curves, and the stimulus to which these phenomena are the response. Either the temperature or the index, it is impossible to say which,

is, to be sure, delayed but that they are both dependent chiefly upon one specific autoinoculation is evident.

Case V is that of a woman with involvement of four lobes and cavity, and symptoms pointing to more or less extensive gastrointestinal complica-

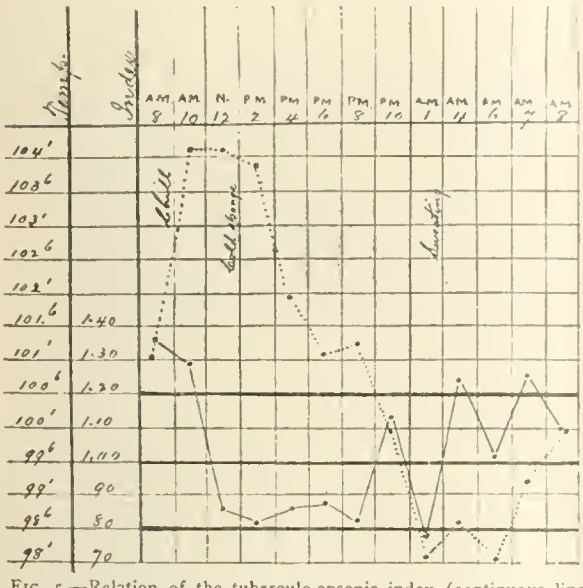

Fig. 5.—Relation of the tuberculo-opsonic index (continuous line) to body temperature (dotted line); (gastrointestinal and septic (?) complications).

tions. This chart (Figure 5) is interesting as showing a marked disproportion between the temperature and the opsonic index, and of itself would lead one to doubt whether the chill, sweat and excessively high temperature might not have been caused by other than tuberculosis, although it cannot be doubted that tuberculo-autoinoculations were at the same time occurring. Incidentally it may be remarked that other clinical symptoms in this case pointed to a complicating pyogenic infection and it is to be regretted that a further study of other than the tuberculo-opsonic index was not made.

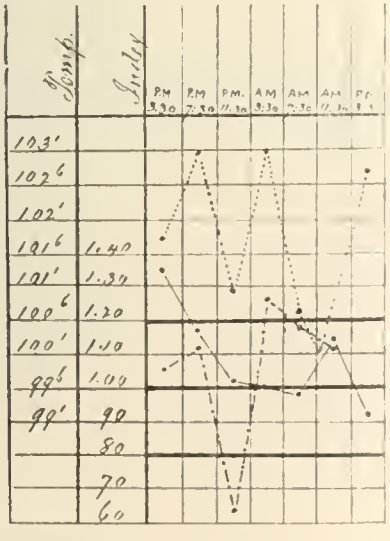

Fig. 6.—Showing staphylococcic (broken line) and tuberculo-opsonic (continuous line) indices in relation to temperature curve (dotted line).

Case VI.—This case is especially interesting in this connection. It is that of a man with involvement of three lobes and cavity, with the very unusual complication of spontaneous thrombosis of the median basilic, ulnar, and popiteal veins. Observations were taken at intervals of four hours from 3:30 on one afternoon to 3:30 on the following afternoon, not only of the temperature and tuberculo-opsonic index but of the staphylococcic index as well, the latter by means of an emulsion of a predominant staphylococcus grown from the

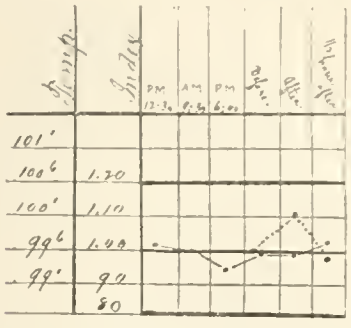

Fig. 7.—Relation of oxidation temperature, following violent exercise (dotted line), to opsonic index in normal (continuous line).

patient's sputum. A study of this chart (Figure 6) will fail to show the usual and, I may say, typical relation of temperature and index either staphylococcic or tuberculous. Of these latter both fall without the normal range and in so far demonstrate the occurrence of autoinoculations from foci of infections by two quite distinct organisms. Such a case is, of course, hardly a fair test of the point at issue. It is, however, suggestive of a reason why an atypical relationship between temperature and index is sometimes found in the acute phases of these advanced and complicated cases other than may be due to exhaustion of the mechanism concerned with the production of specific immunity.

From these and other similar observations it is evident that a more or less typical relationship exists between the temperature and the tuberculo-opsonic index in acute cases of tuberculosis—a relationship which is demonstrable in proportion as the case is one of comparatively pure infection, and becoming less typical as mixed infection predominates. It would seem therefore that a study of the opsonic index in such cases might within its acknowledged limitations be of assistance no less in treatment than in diagnosis.

A study of the foregoing charts will moreover demonstrate the wide range of variation to which the opsonic index is subject at short intervals in cases of active tuberculosis. It is obvious, therefore,

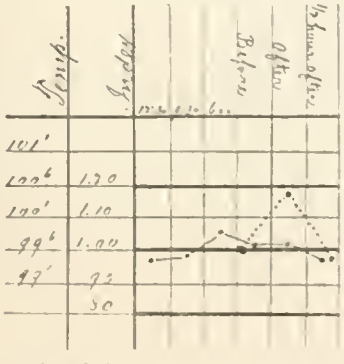

Fig. 8.—Relation of oxidation temperature, following violent exercise (dotted line), to opsonic index in normal (continuous line).

that single observations in such cases may be quite misleading or fail altogether to give valuable information.

The diagnostic value of the tuberculo-opsonic index in cases of suspected or completely arrested

tuberculosis.—It has been, I believe, very generally observed, in this country at least, that in the absence of constitutional symptoms (autoinoculations?) there is no characteristic variation from normal in the tuberculo-opsonic index. A persistently subnormal index is, to be sure, occasionally

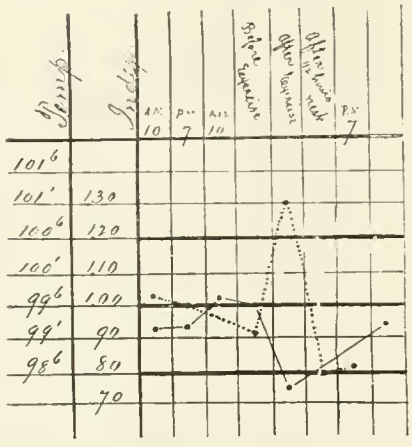

Fig. 9.—Relation of tuberculo-opsonic index (continuous line) to temperature (dotted line), before and after exercise, for diagnosis.

met with in distinctly localized tuberculous lesions of the skin and lymph nodes, but in quiescent pulmonary lesions, whether incipient or otherwise, there is little to be learned from index observations when made in the ordinary way. It has been shown on the other hand, that in the infected organism the specific opsonins are less thermolabile than is the case with a normal serum, and I believe it has been suggested that advantage might be taken of this fact in diagnosis.

It also appears[3] that a more or less marked variation in the index, notably a "negative phase" following upon the subcutaneous administration of tuberculin, may be taken as an indication of the presence of infection.

Neither of these methods, however, seems to have

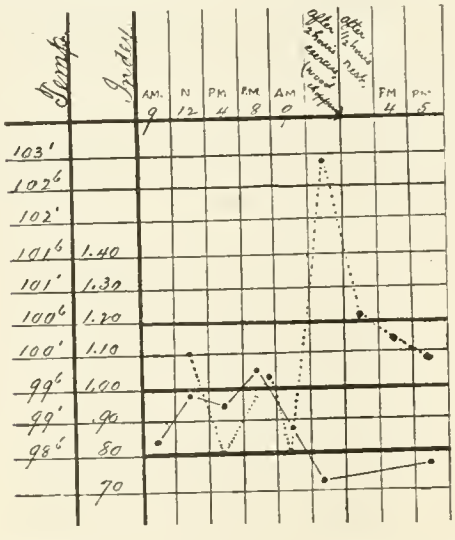

Fig. 10.—Relation of opsonic index (continuous line) to temperature (dotted line), before and after periods of exercise, for diagnosis.

found much favor, and I am not aware that they have been persistently followed or generally adopted.

If in the case of spontaneous autoinoculation from a tuberculous lesion a marked variation in the tuberculo-opsonic index occurs it would be reasonable to expect such a variation to follow upon an artificially produced autoinoculation, and such variation has been shown to occur by Inman working at Brompton Hospital Sanatorium, Frimley.[4] Inman's observations were interesting and up to the time that they were made unique. He demon-

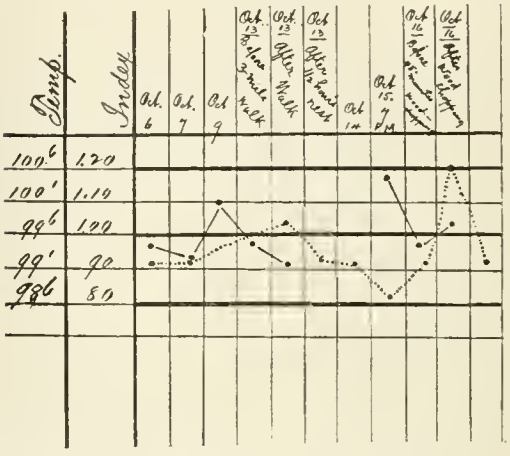

Fig. 11.—Relation of opsonic index (continuous line) to temperature (dotted line), before and after periods of exercise, for diagnosis.

strated very clearly that so long as the case (pulmonary tuberculosis) is not thoroughly arrested, autoinoculations may be artificially produced (in his cases by graduated labor or exercise), which are characterized not only by temperature changes and associated symptoms, but by variations in the index as well. As the disease becomes arrested these phenomena become less marked until in favorable cases they disappear altogether. This, it seems to me, is a point of extreme importance. Means have been long sought by which we might distinguish between a thoroughly arrested (and consequently for the time being at least harmless) tuberculous focus; one which clinically does not require treatment, and a lesion which so far as one

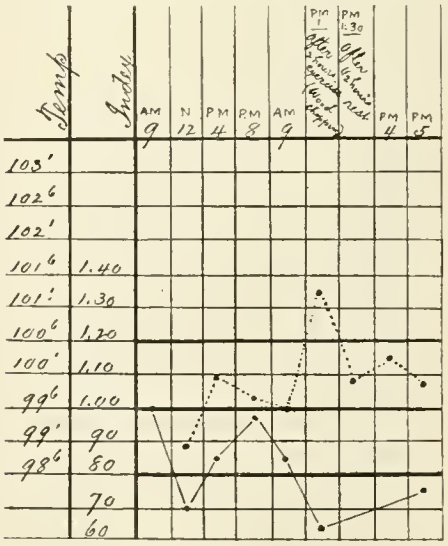

Fig. 12.—Relation of opsonic index (continuous line) to temperature (dotted line), before and after periods of exercise, for diagnosis.

may judge from other available diagnostic methods is apparently identical, but which is in reality only latent and liable to become active on the slightest unusual exertion on the part of the patient.

It would seem that applied with this point in view and in some such manner as that which was

employed in the following experiments, the opsonic index has a most decided value in the diagnosis of incipient tuberculosis, and as an indication for advice and treatment in long standing quiescent cases of the disease.

In the artificial production of autoinoculations caution in two directions is obviously necessary—First, the exercise employed must be sufficient to produce the desired result; and, second, it must not be suddenly carried to a point which in the presence of a "smouldering" lesion might endanger the patient. In other words, the same judgment must be exercised which would dictate a diagnostic dose of tuberculin.

For the first it is well to employ a form of exercise to which the patient is unaccustomed. For instance, if the patient is accustomed to walking from five to ten miles daily without temperature or other symptoms it is unlikely that a demonstrable reaction will follow any "dose" of such exercise within these limits, while it might easily be accomplished by fifteen minutes of such exercise as chopping wood. In fact it is very likely to follow a little vigorous exercise of groups of muscles not ordinarily much used.

For the second it is well to graduate the amount of exercise, both as to time and severity and to apply it in increasing "doses" at intervals until satisfied as to the result. In any healthy individual a more or less marked temperature rise will follow unaccustomed vigorous muscular exercise. This temperature, which for convenience may be termed "oxidation temperature," will quickly subside to or below normal, seldom requiring more than twenty or thirty minutes' rest. When tuberculosis is present, however, and an autoinoculation has been produced by the exercise the subsequent fall is apt to be much slower and if the reaction is at all severe the temperature may remain high for an hour or more and unless absolute rest is insisted upon it may assume a remittent type extending over several days. For the sake of brevity only a few examples of this class of observations are given as these sufficiently illustrate the method pursued.

Cases VII and VIII are those of two normals. These charts (Figures 7 and 8) show a characteristic "oxidation temperature" without variations in the opsonic index following exercise. In both instances here the exercise consisted in a rapid cross-country walk of three miles followed by hard work with a cross-cut saw for forty-five minutes.

Case IX (Figure 9) is that of a supposedly quiescent lesion of one lobe (slight infiltration—bacilli present). Walking three hours (five or six miles) daily produced no demonstrable reaction. As in Cases VII and VIII four index determinations were made prior to the test, which in this case consisted of twenty-five minutes' work with a small axe. "Oxidation temperature" followed and subsided as it might do in a normal individual, but here there was a distinct variation of the index presenting a characteristic reaction.

Case X is that of a young man of twenty-three years with a suspicious history and rather vague physical signs at both apices, on the strength of which he was admitted to the Annex of the Loomis Sanatorium as an "incipient case." His slight temperature quickly subsided and the very scant sputum was nonbacillary. No tuberculin tests were made. The opsonic test was applied to clear up a questionable diagnosis. As will be seen from a study of the chart (Figure 10) five observations were made prior to the test. Following the last observation the patient was given two hours' severe exercise (chopping and sawing wood). Immediately after this exercise, as will be seen, the rectal temperature was nearly 103, while the index had dropped well below the extreme limits of normal. The index, as will be seen, remained low the balance of the day, the temperature gradually subsiding, but not touching normal. I may add, what does not appear on this chart, that the following day, notwithstanding strict rest, there was an elevation of temperature throughout the day and it only reached normal, to remain there, after three days' rest. During or immediately subsequent to this period unmistakable rales were heard at the apices indicating a focal reaction and confirming the diagnosis.

Case XI (Figure 11) is that of a suspected tuberculosis in a woman of thirty-four years. An obstinate cough first aroused suspicion of disease, which a positive reaction from 1.5 mg. tuberculin (subcutaneously) seemed to confirm. At the time of the following tests she had been in the Sanatorium for a month and was practically without symptoms, the cough having disappeared promptly after admission. As will be seen from the chart two tests were made—the first consisting of a rapid three mile walk (she was unaccustomed to muscular exercise of any kind)—the second of the same walk followed by forty-five minutes chopping wood with a small axe. Following the first test the "oxidation temperature" was almost nil. It was more marked after the more severe test as might have been expected. In both cases, however, the index remained within normal limits. On the strength of these observations the patient was allowed to go home, where she has been living under rather more than ordinary strain ever since, but remains apparently perfectly well.

Case XII is that of a young man of twenty-four years with a very suspicious history and general appearance. Questionable signs were discovered at the right apex. No sputum was obtainable. The presence or absence of bacilli, therefore, could not be determined. No tuberculin test was applied. From a study of the chart (Figure 12) it will be seen that even prior to the exercise test there was a spontaneous autoinoculation which, had it been known, would have been sufficient to establish a diagnosis, but, as has been said, the slides were counted in cipher and at the time the low index subsequently found to have been at twelve noon on the day preceding the test exercise could not be placed without vitiating the experiment. The test consisted of the same character and amount (two hours of violent exercise) as in Case X, and in this case also it required more than two days to bring the temperature permanently to normal. Immediately subsequent to the test unquestionable physical signs were made out at the right apex, showing as in Case X a focal reaction and clearing up the diagnosis.

From these and similar observations and experiments conducted in our laboratory Inman's conclusions would seem to be justified and it would further appear that opsonic index determinations may and do have a field of practical value in the diagnosis of early tuberculosis in some respects superior to that of the ordinary tuberculin tests, and finally, that as a means of determining the patient's fitness for discharge from treatment, when

otherwise question might arise, they may be of decided and valuable significance.

ANEURYSM OF THE THORACIC AORTA.*

By ALBERT ABRAMS, A.M., M.D. (HEIDELBERG.)

SAN FRANCISCO.

Spondylotherapeutics.—In the primitive era of hydrotherapy, the application to the spinal region of the hot waterbag and icebag was a conventional procedure dictated by empiricism with little or no physiologic knowledge concerning the action of hot and cold water on the spinal centers. Even at the present day our therapeutic armament includes the indiscriminate application of methods with neither rhyme nor reason. Thus therapeutics is discredited and the results are referred to suggestion; a portentous word, which signifies much or nothing, but usually the latter. The manipulation of definite vertebræ corresponds with the elicitation of definite reflexes, but if the vertebræ are promiscuously handled, counter reflexes are evoked which nullify the reflexes sought. Thus it is, that vertebral manipulation is equally influenced for weal or woe. Modern hydriatists have shown that hydrotherapeutic measures applied in definite regions will influence the viscera; in other words, there is a definite relationship between certain cutaneous and internal areas. The reason why local measures are often efficacious in visceral disease may be explained by Donaldson's theory; the splitting nerve-fiber sends one portion to the viscus and one to the skin overlying it. In 1834, the Griffin brothers of England, published a work in which 148 cases were analyzed showing the relation of certain symptoms to definite spinal regions. These symptoms were associated with spinal tenderness in fixed regions, and they concluded that the tenderness in question was either primary in the spinal cord or secondary to visceral or other diseases. Swedish gymnasts, notably Ling, noted among cardiopaths, tenderness over the fourth or fifth dorsal nerves when this region was subjected to friction.

The Swedish school recognizes definite areas of spinal tenderness identified with the different viscera. In 1841 Marshall Hall published his memorable work which established the importance of the spinal reflex. Brunton cited the fact that clinical experience demonstrated that blisters assuage acute inflammation by inducing contraction of the afferent vessels and thus diminishing tension in the vessels of the inflamed part. As a rule, the site of pain corresponds to the location of the lesion, but in other instances peripheral pains may be caused by diseases of the spinal cord. Reflex or transferred pains may cause an irritation at the origin of the nerve-trunk, and the pain may be referred to its peripheral distribution. The illustrations of Dana show the usual location of transferred pains. In 1893, Head demonstrated that in visceral disease, pain and disturbed sensation may be referred to definite cutaneous areas. Thus one may have a cutaneous expression of visceral disease, which I may call an endogenetic skin-reflex. According to Head, when a stimulus is applied to an organ or tissue with diminished sensibility and which is connected centrally with an organ or tissue endowed with a higher degree of sensibility, the pain is referred to the relatively more sensitive part. Thus it is, that skin tenderness in visceral disease is caused by the passing of sensory impulses from a diseased organ to its corresponding spinal segment; in the latter disturbances are created so that additional impulses coming from the surface of the skin with which this is connected are so modified as to elicit abnormal or painful impressions which in consciousness are referred to the skin, which in the norm has a greater degree of sensitiveness. As a result of Head's investigations, definite cutaneous zones of hyperalgesia associated with visceral disease may be elicited by pressing with the head of a pin or pinching a fold of skin. I employ the vibrations of a tuning fork for the same object, and diminished sensibility (hypalgesia) is as frequently encountered as hyperalgesia. The zones of Head seem to explain the beneficial action of counter-irritation upon deep seated pains. Quincke has collected a number of sympathetic sensations associated with different diseases in which a cutaneous hyperalgesia is also found. Osteopathy ("discovered" in 1874), is founded on the theory that health signifies a natural flow of blood and that the bones may be employed as levers to relieve pressure on nerves, veins and arteries. Despite the contention of the osteopath, the latter in his manipulations of the spinal region unconsciously evokes reflexes which are cogent factors in the treatment of disease. The osteopath indignantly resents comparing his system with massage. Thus, in a representative work on this system by Hulett,[1] the latter contends that masseurs regard the tender spinal areas as secondary to visceral disease, whereas the osteopath conceives them as primary and treats the central point. According to this reasoning, the osteopath regards disease from a central and not a peripheral standpoint. Dowse[9] affirms that ten minutes' work at the spine (by massage) will increase the volume of the pulse more than an hour's work at the body, as a whole, the spine being omitted.

The Vertebral Reflexes.—In medical literature the author has repeatedly referred to certain visceral reflexes evoked by cutaneous irritation; viz., the lung reflexes of dilatation[2] and contraction,[3] the heart reflex,[4] liver reflex,[5] stomach and intestinal reflexes[6] and the aortic reflexes,[7] which later will be the special subject for our discussion. The reflexes in question have more than physiologic interest, insomuch as the visceral reaction may be utilized in a diagnostic and therapeutic direction. The evidence heretofore adduced of the results achieved by electric, hydriatic, mechanic and the balneary treatment of disease, was naught else than a mere array of words conceived in conjecture only. Others less inclined to hypothesize sought an expeditious solution by referring their action to suggestion. The recognition of the visceral reflexes is more than an apologetic attempt to relegate the therapeutic methods in question to their proper sphere of action. If one doubts the existence of vertebral reflexes, let me direct your attention to a very simple expedient which I have only recently observed. While palpating, say the radial pulse, make firm pressure at the vertebral exit of the spinal nerves (preferably at the side of the upper dorsal vertebræ) and you will note a decided alteration in the character of the

*An address by invitation before the Alameda County Medical Association, Feb. 16, 1909.

pulse, which often amounts to inhibition of the latter. Reference to Fig. 1 shows a number of central reflexes which may be elicited by concussing definite vertebræ. The latter are bilateral. I cannot enter into a thorough discussion of this subject, but must refer you to my original contribution.[10] I may, however, demonstrate the biceps, triceps and wrist-jerk and the adductor reflex. The first combination of reflexes is obtained by concussion of the fifth and sixth cervical vertebras. To elicit this

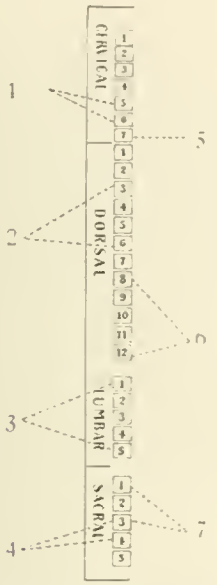

Fig. 1.—Vertebral concussional reflexes, showing the vertebræ to be concussed for their elicitation; 1, biceps and triceps reflexes and wrist-jerk; 2, pectoral and epigastric reflexes; 3, gluteal and adductor reflexes, cremasteric reflex from the 1st to the 3d lumbar vertebra; 4, plantar reflex; 5, aortic and cardiac reflexes of contraction (pressure at the vertebral nerve exits will inhibit heart); 6, aortic and cardiac reflex of dilatation; 7, gastric, intestinal, hepatic and splenic reflexes of contraction.

reflex the upper extremities must be placed in a state of flexion, the elbows resting in either hand of an assistant: if the patient does not thoroughly relax the muscles while the spines in question are concussed, no reflexes will be elicited. Very often this reflex is better elicited if the patient allows his elbows to rest on a table with arms flexed and hand dropped so as to achieve thorough relaxation. To obtain the adductor reflex, the patient sits in a chair with legs extended and relaxed during the time any of the lumbar vertebras are concussed. To obtain the concussional vertebral reflexes for diagnostic purposes, the writer employs a strip of linoleum (about 6 inches long and 1½ inches wide) and a hammer (Fig. 2) with a large piece of thick rubber such as is used by French clinicians for eliciting the knee-jerk.

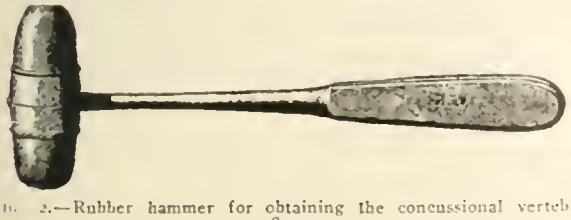

Fig. 2.—Rubber hammer for obtaining the concussional vertebral reflexes.

One may also strike the spinous processes indirectly by placing the palmar surfaces of the fingers in contact with the vertebral spines and, with the clinched fist, the dorsal surfaces of the fingers are struck a series of forcible blows after the same manner in using the hammer. The method with the hammer is preferred.

The Aortic Reflexes.—The course of the upper surface of the normal aorta in the adult of middle life may be projected on the thorax by drawing a curved line, beginning at a point corresponding to the right sternal line in the middle of the first intercostal space and ending at the point of insertion of the first left rib to the sternum. The highest point of the aortic arch is distant about 5 cm., and the beginning 2 cm. from the anterior thoracic wall, hence a forcible percussion blow (which is propagated to a depth of 5 cm.) cannot fail to elicit the dullness of the aortic arch if dilated. If the aorta is of normal size, dullness does not extend beyond the edge of the sternum on either side. Concussion of the four last dorsal vertebras (8th to the 12th dorsal vertebra) in succession by a series of sharp vigorous blows will in the norm dilate the thoracic aorta, which can be demonstrated by the *x*-rays and by percussion. Percussion must be executed at once after concussion of the vertebral spines, insomuch as the duration of the reflex of aortic dilatation is limited (from one-half to one minute). Concussion of the spine of the seventh cervical vertebra causes a contraction of the thoracic aorta (aortic reflex of contraction). Thus it is, that when one provokes the dilatation reflex, the counter reflex of contraction dissipates at once the former reflex.

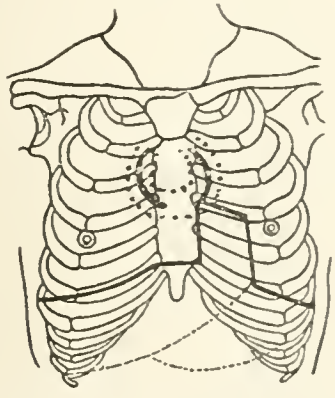

Fig. 3.—Aortic reflexes of contraction (dotted lines within continuous line) and dilatation (dotted lines without continuous line) in the patient of Dr. Sanderson with an aneurysm of the thoracic aorta.

Postural Lung-Dullness.—The author has recently observed that posture influences lung-resonance. If one percusses the anterior chest in an individual first

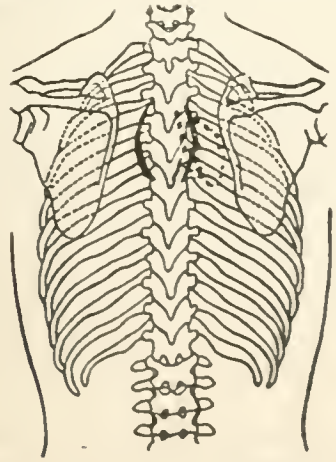

Fig. 4.—Posterior view of same patient (Fig. 3). Note that in this illustration only one part of the aneurysmal wall responds to the reflex of dilatation, a not infrequent phenomenon when aneurysms have attained some magnitude.

in the erect posture and then when the patient leans very far forward the resonance in the former posture is translated into dulness in the latter posture.

Similarly, the lungs become dull when the patient leans backward or to the side. In other words, the writer believes that the pulmonary vessels being unprovided with vasomotor nerves, permits of the gravitation of blood in the lungs in the direction of the posture of the patient, and that the dulness is due to an increased quantity of blood in a given area. The author further believes that many so-called cases of lung-atelectasis are in reality areas of lung congestion, and the differential diagnosis is as follows: In atelectasis, the area of dullness will disappear after repeated forced inspirations or by elicitation of the lung reflex (vigorous rubbing of the skin over the area); whereas in congestion (say the dullness is in the posterior portion of the thoracic region), the dullness will not completely disappear until the patient is placed in the prone posture. The author has noted furthermore, that when the patient leans far forward (so that the trunk is almost at right angles with the hips), the dullness over the upper anterior surface of the thorax corresponds with the dullness of the aortic arch elicited by the aortic reflex of dilatation.

The Aortic Reflexes in Diagnosis.—As before remarked, one is able to define by percussion the normal area of the arch of the aorta after concussion of the four lower dorsal vertebræ and a similar area of diminished resonance or dullness may be elicited when the patient leans far forward. Thus it is that, if the diminished resonance or dullness exceeds the norm, either the vessel is dilated or the site of an aneurysm. One may remark that if an aortitis is present, the reflex of dilatation will reproduce the symptoms peculiar to this affection, viz., pains in the upper sternal region extending through the mediastinum and to the shoulder and arm.

A dull area in the upper thoracic region or in the back (corresponding to the site of the aorta) if caused by a thoracic aneurysm, will show a diminished area of dullness when the spine of the seventh cervical vertebra is concussed (aortic reflex of contraction) and an increased area of dullness when the spines of the four lower dorsal vertebræ are successively concussed (aortic reflex of dilatation). Up to the present time of writing the author has examined 42 cases of aneurysm of the thoracic aorta and has noted an absence of the reflex in only two patients in whom the aneurysm had attained enormous dimensions. All these cases were controlled by skiascopic examinations. With the latter one may note a contraction and dilatation of the aneurysmal sac when the spines of the special vertebræ are concussed. One may also observe an immediate evanescence of pressure symptoms (dyspnea, cough, and pains) when the sac is brought to contraction after a single séance of vibration treatment applied to the spine of the seventh cervical vertebra.

The Aortic Reflex of Contraction in Treatment.—It occurred to the writer, when he first employed the aortic reflexes in diagnosis, that, if concussion of the seventh cervical vertebra would cause contraction of an aneurysmal sac, this fact would prove advantageous in the treatment of a thoracic aneurysm. The results achieved have exceeded the author's expectations. Only five patients with thoracic aneurysm have thus far been treated by the author according to his method, but they were all advanced cases. Absolutely no results were achieved in one case. This much may be said for this treatment that, unless the results are immediate, nothing can be expected from its continuance. The first case of aneurysm of the thoracic aorta thus treated was seen in consultation with Dr. Sanderson, a member of your association. The following record is presented:

Treatment was commenced July 7, 1905, on which date the patient complained of violent pains in the chest and dyspnea on the slightest exertion. On Aug. 2, 1905, the *x*-ray shadow of the aneurysm was denser, and the aortic reflexes could not be elicited. The latter I attributed to clot-formation in the aneurysmal sac, which inhibited whatever elasticity remained in the aortic walls. At this date aneurysmal pulsations could no longer be detected by the rays. Dulness formerly present over the sac on the anterior chest wall could no longer be elicited. Tracheal tugging was barely perceptible. The thoracic pains had disappeared and there was no longer any dyspnea on exertion. On the first of September, Dr. Sanderson stated that the only symptom which remained at the time the patient left for his home was slight tracheal tugging. In all my cases the latter symptom persisted despite the disappearance of subjective symptoms. I will not weary you with a recital of the histories of the other patients, but will content myself by presenting to you a patient of Dr. Rowell, a member of your association. About four years ago this patient first noted the appearance of the following signs: Cough, pressure in the chest, dyspnea, and a sensation of suffocation when he assumed the recumbent posture. Just before treatment was commenced the patient could not get more than three hours' sleep at night owing to paroxysmal attacks of coughing and choking. After the first treatment he could sleep the entire night, and to-day, after two weeks' treatment, consisting of daily séances (five minutes duration) by means of vibration applied to the seventh cervical vertebra, the patient is practically well and there is nothing to indicate the persistence of his original trouble beyond slight tracheal tugging. During this brief period he has shown a gain of ten pounds in weight.* Now, a few words are necessary respecting the method of treatment. In the therapeutic elicitation of the vertebral reflexes, notably, the aortic reflexes, the vibratory apparatus which the physician must employ is the one giving the percussion stroke. All other motions, such as oscillations, shaking, and friction interfere with results; in other words, select an apparatus which percusses. First dust some talcum powder over the site of the spine of the seventh cervical vertebra to avoid irritation from friction of the pad connected with the apparatus; next cover the spine of the vertebra with several layers of lint which are attached to the skin by adhesive plaster. After this, the percussion stroke may be communicated directly to the spine of the seventh cervical vertebra, or indirectly, if the skin is sensitive by interposing a strip of linoleum. The daily séances, according to results, may last from five to fifteen minutes, but during the séance the treatment must be interrupted from time to time to avoid irritation of the skin. The latter may be avoided if the operator directs the patient to

*Since this address was delivered, three other cases of thoracic aneurysm were successfully treated by the same method. One of the patients referred to me by Dr. W. A. Clark of San Francisco with an enormous aneurysm was practically discharged after five weeks' treatment. The author has not the hardihood to regard his method as curative, for time alone is the decisive factor, yet a conservative estimate of the results prompt him to say that, as a palliative method, it surpasses any which has yet been introduced. The practical employment of the aortic and other reflexes will be embodied in a book on spinal therapeutics, which will be published shortly.

inform him the moment a burning sensation is experienced. Perhaps the best of all methods for eliciting the reflexes is the employment of a plexi-meter (a strip of linoleum) applied to the seventh spine, which is struck a series of rapid and moderate blows by means of a hammer, to the end of which is fixed a large piece of hard rubber (Fig. 2). By the latter method all the vertebral reflex are most surely evoked. It is wise in this method as well to protect the spinous process with a thick layer of lint.

Physiology of the Aortic Reflexes.—Claude Bernard's interesting observations advanced the clinical study of vasomotor phenomena. He found that when the sympathetics in the neck of a rabbit were cut, the blood-vessels in the ear on the corresponding side became dilated, and that if the peripheral ends were stimulated the ear became blanched. Those who are adepts in manual therapy find that manual pressure along the vertebral column will evoke either vasoconstriction or vasodilation; the former, by brief, and the latter by continuous pressure. It is evident that in explaining the genesis of the aortic reflex of contraction one is concerned with stimulation of the vasoconstrictor nerves, the centers of which are chiefly in the medulla, where they pass into the cord and emerge with the anterior roots as preganglionic sympathetic fibers. These fibers are not only capable of altering the caliber of the vessels, but by means of continuous stimuli passing over them they maintain the tone of the vessels.

The aortic reflex of dilatation is associated with stimulation of the vasodilator nerves, the reflex centers of which are located in the medulla and throughout the spinal cord. From the latter situation they emerge with the posterior spinal nerves. The author seeks to explain the aortic reflexes by either stimulation of definite vasoconstrictor and vasodilator nerves or their centers in the cord, and he has established empirically that concussion of the seventh cervical vertebra stimulates the aortic constrictor nerves, whereas the dilator nerves are excited by concussion of the spines of the four lower dorsal vertebræ.

The Psychology of Clinical Observations.—When the author published his original communication on the subject of the aortic reflexes, he was the recipient of many letters, the burden of which represented the inability of the correspondents to confirm the observations of the author. It was impossible to answer all the communications at that time, and as this is an opportune moment, I will now endeavor to answer some of them. One of the most eminent physiologists in this country protested that, considering the pathologic condition of the walls of the aorta in aneurysm of that vessel, it could not in consequence be excited reflexly to alternate contraction and dilatation. Again, such clinical observations could not be accepted unless corroborated by physiologic investigations. No one can gainsay the fact that pulsation is an important sign of an aneurysm and, insomuch as this phenomenon is dependent on the elastic recoil of the walls, it follows that elasticity of the vessel is not annihilated in aneurysm of the vessel. It is true, as the author has frequently observed, that the walls of the aneurysm do not contract nor dilate equally in eliciting the aortic reflexes; in fact, there may be no perceptible change under the influence of the reflexes at one point, but a decided change at another point, although in practically every instance some perceptible change was observed. Theoretically at least, the aortic reflex will persist as long as the aneurysm pulsates. The clinician no longer regards the pronunciamento of the physiologist as apodictic. We have learned to discredit many statements emanating from the laboratory investigator, not so much because the observations of the latter are faulty, but because there is a considerable difference between a laboratory and the bedside and a guinea pig and patient. Many of the facts derived from the laboratory suggest the comment of the mathematician, who, having demonstrated a new mathematical theory, thanked God that it could not be of the slightest utility to any living soul. Neither the pathologist nor the physiologist should forget that "pathology is the physiology of the sick." The presence of bronchodilator as well as bronchoconstrictor fibers in the vagus was conclusively established by the physiological investigations of Dixon and Brodie[14] in 1903, yet as A. G. Auld observes,[15] "It undoubtedly stands to the credit of Abrams to have proved, at least seven years since by a simple clinical observation,[16] that the vagus must contain bronchodilator as well as bronchoconstrictor fibers."

The final court of decree of the clinician is neither the physiological nor pathological laboratory. To test a given function one must compare it with a like function in individuals of the same species. Thus, if the same quantity of uric acid were excreted in a mammal as is excreted in a normal bird, it would have to be regarded as pathological. If disease were wholly a question of demonstrable lesions then the pathologist would be compelled to deny the existence of the so-called functional diseases. In consequence of this conflict between the laboratory and clinical investigator a hiatus has arisen which is now occupied by clinical pathology, a branch which endeavors to conciliate scientific and empirical medicine. Several years ago, the writer observed that one could make a record of the pulsations of the head, and furthermore, that the cephalograms thus obtained in certain subjects were pathognomonic of cerebral arteriosclerosis. Investigating this subject further in the physiological laboratory of the University Hospital, London, and in Paris, the writer did not obtain the slightest clue to the cephalic pulsations, and he questions whether he is justified in rejecting a clinical observation which does not permit of physiologic demonstration in animals. One vituperator condemned my method of treating aneurysms as absurd, because it was not responsive to reason. My vituperator recalled the erudite German professor of economics who received a bed as a present. Until the small hours of the morning he busied himself with abstruse calculations to determine whether he was large enough for the bed, or if the latter were large enough for him. Finally, he was struck with the happy idea of getting into the bed, and to his intense delight discovered that it was admirably suited to his proportions. If my detractor were endowed with the true scientific spirit, he would not have condemned a new method of treatment without a trial, considering the kaleidoscopic changes constantly arising in all branches of science. The scientist rejoices one day at the birth of a new theory and officiates at its burial on the morrow. In 1903, in several issues of the London *Lancet*,[11] a discursive polemic was agitated on the subject of my "lung reflex." It was quite evident that one of the disputants did not rigorously execute the method for eliciting the reflex in question, but failed to cite this reason for con-

demning it, although others employed the reflex as a clinical sign of value.[12] Many new methods for a like reason have been relegated to oblivion. Sometime ago, while in Paris, the writer found several clinicians who elicited the heart reflex[8] as a routine method of examination, and appeared quite content with the sign. The writer demonstrated that the sign as elicited was of no value, insomuch as when the precordial region was stimulated it likewise evoked the lung reflex, which also diminished the area of cardiac dullness, and that in consequence one could only rely on the deep area of cardiac dulness as an index of myocardial retraction. A prominent Eastern clinician spent several days at the author's office investigating visceral reflexes. One of the patients submitted had an aneurysm of the thoracic aorta. Here the aortic reflexes were the object of study. It was impossible to convince the clinician that there was any modification of the area of dulness after the elicitation of the reflexes, until the writer compelled him to close his eyes while percussing, when the results of percussion tallied. To the detriment of skillful percussion, instrumental has supplanted the finger-finger percussion. This is an egregious error, considering the fact that in percussion the adroit physician is guided not by what he hears as by what he feels. A word is permissible concerning percussion of the chest. When one percusses the normal chest, the sound is the product of the vibration of the lung tissue and the thoracic walls (notably the sternum, which is essentially a sounding board). It is the summation of this vibration which interferes with the elicitation of the dullness of the airless organs in juxtaposition to the lungs. If this vibration in question can be eliminated the definition of airless structures like the organs, tumors, aneurysms, etc., proves easy of attainment. This writer has referred to this method as vibrosuppression.[13] It is best achieved if percussion is executed during the time the patient has suspended respiration after forced expiration and while the vibrations of the sternum are inhibited by firm pressure on the lower end of the bone by the hand of an assistant.

Tonsillectomy Notes.—There is less danger of injuring the deep tonsillar vessels if the pressure is made from inside with the instrument than when it is exerted on the outside. Hard tonsils with much connective tissue are better removed by a cold snare than by a sharp instrument, as less bleeding occurs. An hypertrophied lingual tonsil sometimes causes the discomfort of a heavy, sore feeling at the base of the tongue. This may be sufficient to indicate removal.—*American Journal of Surgery.*

ATRESIA OF THE VAGINA.

WITH REPORT OF A CASE COMPLICATED BY HEMATOTRACHELOS—OPERATION.

By OLIVER C. SMITH, M.D.,

SURGEON TO HARTFORD HOSPITAL,

AND

PAUL H. WATERMAN, M.D.,

HARTFORD, CONN.

Case.—E. G., 14 years, German; attends school. Family history negative. Only serious illness smallpox at 6 years, with mild cutaneous symptoms. Patient has never menstruated. Enjoyed good health until four weeks ago, when she suffered from mild abdominal pain, with slight fever, lasting two days. Her present illness is a recurrence of abdominal pain and tenderness, with slight rise of temperature and pulse.

Condition at time of examination, at New Britain Hospital: A well-nourished, apparently well-developed girl, timid and nervous. Pulse, 90; rectal temperature, 100° F. Examination of heart and lungs negative. Abdomen moderately distended, general tenderness, more pronounced over right lower quadrant. Dullness on percussion in flanks and over lower abdomen. To the right of the umbilicus, extending 5 cm. above, and 4 cm. below, is a hard, elongated mass. Blood examination not made. Rectal examination reveals fluctuating mass in pelvis. Imperforate hymen. Vaginal examination not attempted. Diagnosis, probable appendical abscess.

Operation, New Britain General Hospital, November 11, 1908. Laporatomy. A 7 cm. vertical incision was made through the right rectus, over the tumor. The hard mass was found to be the body of the uterus, twice to three times the ordinary size, otherwise of normal appearance. Tubes and ovaries were congested, otherwise normal. Continuous with the lower end of the fundus of the uterus, spreading out symmetrically like a skirt, was a large, thick-walled cyst, filling the lower part of abdomen and pelvis. One thousand five hundred c.c. of thick, dark blood was removed by aspiration through the tube introduced into the incision made in the cyst. The wall of the cyst at site of incision was sutured to the peritoneal edge of the abdominal wound. Abdomen closed except at this point. Cyst drained through abdominal wall with large rubber tube. Patient was placed in lithotomy position and entrance made through the imperforate hymen and perineal tissues by combined sharp and blunt dissection, the only trace of vagina found being a cord of fibrous tissue. A long probe was introduced through the drainage tube from above, until it could be felt by the finger in the perineal wound. Incision from below was then made into the cyst cavity upon the probe as a guide. The lower end of the drainage tube was then drawn down beyond the vulva. The patient rallied well from this operation. There was some drainage of thick blood from above and below, for several days.

Three weeks later the abdominal wound was reopened, the cyst wall separated from its parietal and omental adhesions. The fundus of the uterus was now found to be of nearly normal size, retroverted, dipping down into the pelvis. The enormous blood cyst had contracted to a narrow cylindrical tube leading into the pelvis and was clearly the elongated cervical portion of the uterus. A drainage tube was introduced into this canal, the

upper end sutured to its inner surface at the site of the original incision. This served as a means of traction in drawing the uterus down into the pelvis. This opening in the cyst, or cervix, was closed by a double row of Lembert sutures of fine linen. The abdominal wall was closed by tier sutures with small

Fig. 1.—Condition at the time of the first operation.

cigarette drain. Henceforth, drainage was from below.

The patient reacted well, and upon examination two weeks later the artificial vaginal canal was found to be 6 cm. in length, and 2 to 3 cm. in diameter, terminating in its upper extremity at what now appeared to be a comparatively normal, although dilated, os uteri.

At the present time the patient is wearing a drainage tube extending from the vulva to within the cervix, for the double purpose of preventing contraction and providing drainage. The operation for construction of a permanent vagina is contemplated as soon as consent can be obtained from the patient's parents.

Adopting the views of Nagel, Veit, and Meyer, this is a case of acquired atresia. The history of smallpox strengthens the probability of this mode of origin.

The comparative rarity of this condition justifies the report of all individual cases and the divergence of opinion in regard to its etiology invites a careful record of the findings in each case. Full and satisfactory discussion of the subject, especially from an operative standpoint is found in few recent gynecological treatises. An article by Brothers[1] covers the history of operative procedure in this condition, and in regard to the construction of an artificial vagina concludes that, while the best results are obtained by the use of the rectum or sigmoid, in whole or in part of its calibre, as recommended by Snegireff,[2] Gersuny,[3] Federow,[4] and Baldwin,[5] yet transplantation of skin or mucous membrane is to be preferred, because it is a simpler operation and does not disturb the normal structure of other organs. The use of a loop from the lower ileum was later suggested by Baldwin,[6] and also by Haeberlin,[7] which would seem to offer the best results, as promising greater permanence and approximating the normal structure most closely, although it entails a more serious operation than might be justified in some cases.

Much has been written of late years upon the etiology of this condition, the preponderance of opinion at present inclining to the view of Nagel,[8] Veit,[9] and Meyer,[10] that all simple vaginal atresias, that is, where there is no coexistent defect in other genital organs, are acquired, or to the view of Küstner,[11] that such atresias, even if present at birth, are the result of inflammatory or traumatic insult received during intrauterine life. Good discussions of this question are contained in articles by Thienhaus,[12] and Gellhorn.[13] The coexistence of uterine malformation is thus made determinative of the simple primary origin of the vaginal defect, although Fromme[14] proposes the view that developmental anomalies of uterus and tubes may occur in the fetus as the result of vaginal defect. The present writers do not find justification for such widely inclusive statements. Arrested or misdirected development may occur in embryological life and the structure of the vaginal and uterine "Anlage" renders them particularly liable to such defective growth. There seems to be no adequate reason to deny that a defect may occur primarily in some one part of the Müllerian ducts, as well as in the whole of their length.

A surprisingly large number of cases of vaginal atresia have been reported and collected by various writers. Neugebauer[15] collected 1000 cases in 1895, almost one-half of which were definitely acquired, while in 300 others the history gave no evident inflammatory or traumatic cause for the condition. In a large number of cases recorded, the report is so scant in details that few conclusions are justified. The writers have found records of 37 cases in the literature of the last eight years, whose report was sufficiently detailed to warrant analysis in this regard; and as far as was known, all of these cases were congenital. In 17 cases there was complete or almost complete atresia (almost complete in that there was a slight depression at the vulvar orifice of the vagina), of which 8 had normal uteri and 9 had defective uteri; 20 cases showed partial atresia, in the form of complete occlusion of the canal above or below a certain level, or of an occluding transverse septum of varying thickness, situated at any level of the canal from cervix to hymen. In 6 of these cases the obstruction was in the upper part of the tract, in 7 cases in the lower, and in 7 the atresia was termed hymeneal, but in 4 of these latter cases the description of the findings was too indefinite to warrant confident acceptance of the term. In the higher atresias the uterus was normal in 1 case and defective in 5, in the lower forms normal in 6 and defective in 1, and in the hymeneal forms normal in 4 and defective in 3; thus 11 of the 20 cases present normal uteri and 9 show uterine defect. In the complete forms the uterus was absent in 5 cases, rudimentary in 2, and bicorn in 2; in the partial atresias occupying the upper part of the tract the uterus was absent in 3 cases and rudimentary and one-horned in 1 each; in atresias at a lower level it

was absent in 1 case and normal in all the others; and in the atresias recorded as hymeneal it was bicorn in 2 and infantile in 1. Absence of both uterus and tubes occurred 5 times, being found in 3 cases of complete atresia and in 1 each of the upper and lower types. The ovaries were absent in

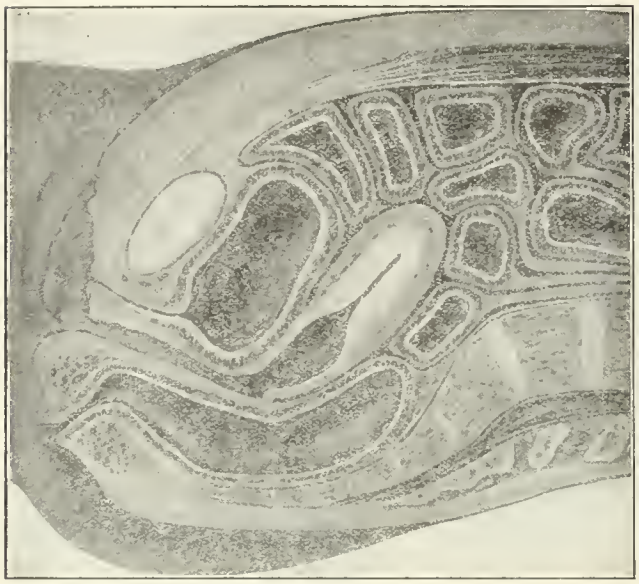

Fig. 2.—Condition six weeks after operation.

4 cases in conjunction with lack of uterus and tubes, 3 of these cases presenting complete atresia and 1 the lower form, while tube and ovary were absent on one side in a case of complete atresia. Ovarian defect involves developmental disturbance of a separate embryological structure, the Wolffian body, and hence is an infrequent coincidence. Coexistent anomaly in other organs developing from this body is still more infrequent. In one case the kidneys were abnormal, being joined into one body, somewhat in the horseshoe manner, and in one other case, recently operated by Dr. W. J. Mayo, the ovary on one side was lacking, while there was no kidney or ureter on the other side.

Bearing in mind that we are discussing atresias probably present at birth and certainly not acquired after development of the menstrual function, and using the cases of the present series as the basis of argument, we might draw the following conclusions: Uterine defects occur in a little less than one-half of all cases; there is, approximately, an even chance of the coexistence of uterine defect with any given form of atresia; there seems, therefore, to be no ground for asserting that a certain vaginal malformation is acquired, when it exists alone, unassociated with other genital defects, when it would be regarded as primary if other genital defects were present.

This aspect of the question does not affect the surgeon in any degree, all atresias of early origin, whatever their cause, presenting practically the same problems. Practical conclusions can, however, be drawn from our data. It is seen that the more extreme defects of the upper genital tract occur in the more extensive atresias; that the percentage of grave uterine defect is almost as great in the partial atresias occupying the upper part of the vagina; that in this latter form the percentage of occurrence of uterine defects in general is much greater; and that in atresias of the lower vagina, while serious defects may be found in the other organs, yet their percentage of occurrence is very small, the more common defects being slight in degree.

As a rule, the surgeon's attention is first directed to the individual case of vaginal atresia by the untoward symptoms that arise from the damming back of the menstrual blood. His first indication is toward immediate relief of the obstructed fluid, since without surgical interference the outcome is almost certain to be fatal. This operation does not of itself entail great difficulty, but the second indication immediately presents itself, namely, the establishment of conditions under which the patient's life may be continued in a manner approximating the normal as nearly as possible. The determination of these conditions will affect the form of the primary operation. The most desirable conditions naturally involve the existence of properly functionating ovaries, tubes, uterus, and vaginal canal. As we have seen, there is slightly more than an even chance in any case of vaginal atresia—19 to 18, to be exact—that all the other genital organs are quite normal, so that the surgeon's secondary operation in one-half of all cases will have as its sole goal the construction of a satisfactory vagina. If defect does exist elsewhere, the chances are just even that the uterus will be absent. In this case there is definite indication for oophorectomy, unless the abnormal menstrual molimena cause no particularly untoward symptoms. A peculiar case is reported in which, in absence of the uterus, a hematoma was gradually formed in the pelvis, into which entrance was finally made along the path of the atresic vagina, and through this channel menstruation occurred thenceforth.[16] If the operator were to accept forthwith the recommendation of various writers, to the effect that there is no indication to construct a vaginal passage when the upper genital organs are defective, the necessary corallary of this being extirpation of uterus, tubes, and ovaries, then this radical step would need to be taken in 49 per cent. of the atresias of the type under discussion and much unnecessary harm would thus be done. For if uterus and tubes are present, no matter their state, there is strong probability that they can become capable of performing that part of their function relating to menstruation, if not that involved in pregnancy. One should hesitate, moreover, before declaring that a certain uterus is not fitted for successful pregnancy; children have been delivered from uteri presenting various types and grades of malformation and we have the testimony of Emmet[17] that rudimentary uteri and tubes may develop to a functionating condition after the vaginal atresia has been repaired. Emmet's statement has, however, been contested by various writers. It is thus seen that a clear conception of the condition of the genital organs must be obtained before even the first steps are taken to relieve the primary or secondary symptoms of vaginal atresia. To obtain this, abdominal section is the only satisfactory procedure, as has been urged by Saenger,[18] Pfannenstiel,[19] Halban,[20] and others.

Other considerations affecting the choice of operative method are found in the nature of the hematoma arising from obstruction to complete discharge of menstrual fluid. Out of 41 cases described in detail, a hematoma was present in 27. Hematocolpos was found in 14 cases, or 52 per cent., existing alone in 3 cases, and associated with hematometra in 6, and with hematosalpinx in 5 cases. In 19 of these 41 cases there was, however, no vaginal canal from cervix downward, and in 6 other cases

there was no canal at the upper end of the vagina, thus leaving only 16 cases in which hematocolpos could possibly develop. A case is recorded in which the vagina was absent, where the uterus expelled the blood into the pelvic tissues between bladder and rectum, forming an artificial sac,[19] but it is probable that the cervical canal or, at least, the external os, is occluded in nearly all the cases where the vaginal atresia involves the upper portion of the vagina.

Hematometra occurred in 23 (85 per cent.) of the cases, existing alone in 7 cases, with hematocolpos in 10, and with hematosalpinx in 9 cases. The uterus was the seat of the hematoma in all but 5 of the cases in which its structure was normal (in these 5 cases the atresia was of the hymeneal type, so that a large hematocolpos formed, and in one of these cases there was a large hematotrachelos), and in 5 cases where it was abnormal, its structure in these cases being rudimentary or bicorn.

Hematotrachelos was reported in 3 cases only. In 2 of these there was no trace of the upper vaginal canal and the external os was apparently occluded; there was a normal uterus with hematometra in 1 case and a rudimentary uterus in the other. In the third case there was a large hematocolpos, but no hematometra, although the uterus was normal. It may well be that indefiniteness of statement exists in this regard and that the cervical portion of the uterus was dilated in some cases where the condition was reported under the inclusive name of hematometra, because it has been generally supposed that in a large majority of cases the cervix becomes distended before the uterus.

Hematosalpinx was found in 11 cases, 27 per cent., being bilateral in 6 cases and unilateral in 5. The tubes were, however, absent in 9 cases, thus giving 34 per cent. of hematosalpinx in cases where the condition was possible. Puech found a tubal blood-sac in 18 out of 258 cases of vaginal atresia. It is thus seen that the tubes are involved in one-third of all cases where they are present, in more than one-third of cases of hematocolpos, and in almost one-half of cases of hematometra. Surgeons of earlier days were compelled, by the limitations of their surgical technik, to relieve the secondary symptoms of vaginal atresia by the perineal or vaginal route and one is amazed to note the high mortality in an operation which, at first glance, would seem to be comparatively safe. A mortality of 70 per cent. was given by Fuld,[22] 39 out of 56 cases dying after this operation. In a majority of cases death was due to septic peritonitis following rupture of the tubes during or after operation. This danger has been pointed out by various writers,[23, 24]. Some doubt exists as to the mode of origin of the tubal hematoma. Many writers regard it simply as a reflux from the distended uterus, but it is highly improbable that this is the case. If such a reflux were possible, it would be found more commonly in other conditions of obstructive dysmenorrhea, but this seldom or never occurs. The uterine end of the tube has been found closed in several cases,[12, 25], and it is probable that mechanical obstruction exists at this point in all cases of hematosalpinx and that the condition is due to congestion from pressure in the uterine wall, as occurs sometimes in myofibromata.[26] It is highly improbable that the tubal blood arises from primary tubal menstruation, since it is questionable if such a process ever occurs. Moreover, if the condition were due simply to reflux or to tubal menstruation the blood would escape through the ostium abdominale into the peritoneal cavity, an occurrence which has never been recorded. Occlusion of the fimbriated end of the tube has been observed in numerous cases,[12, 27], and it is probable that such an occlusion exists primarily in all cases of hematosalpinx, as a result of some previous inflammatory process. The evidence which this gives of the pre-existence of inflammation at some point in the genital tract has been used as an argument in support of the view that the vaginal atresia is the result of an inflammatory process, regarding the atresia of the vagina and of the outer end of the tube as the result of the same process.[25] Whether as a result of the previous inflammatory process or not, adhesions form between the tube and adjacent structures, a condition which readily leads to rupture of the delicate walls of the sac under the slightest disturbance of the relative positions of the various organs[28]. Hence rupture has occurred during vaginal, rectal, and abdominal examination, but its most common cause is the more or less blind procedure in vaginal or perineal operation and in the emptying of the hematoma in vagina or uterus from below. Repeated experience with tubal rupture and subsequent peritonitis led earlier writers to recommend gradual emptying of the blood sac, but the utmost caution cannot give positive safeguard against tubal rupture when operating from below. Torsion of the tubal blood-sac has been noted in 3 cases,[29] a condition which increases the liability of rupture. Hence, since hematosalpinx occurs in about one-third of our cases and of itself may rapidly lead to a fatal condition, operation is indicated at the earliest possible date, especially since its existence cannot always be exactly determined by manual examination and since such examination may be dangerous. Moreover, since operation by the vaginal or perineal route may have serious immediate or secondary results, laparotomy is the only safe procedure, as has been urged by several writers for various reasons,[30, 31, 32]. Extirpation of the tube is generally regarded as the operation of choice in this condition, but emptying by simple incision followed by repair has proved successful in enough cases to warrant its attempt in cases where the other organs can be preserved in a functionating condition, especially in case the other tube is defective or diseased. There is, of course, small chance of conception through the agency of the affected tube, since we have assumed that closure of its outer end is present in all cases.

A not inconsiderable difficulty often arises in the vaginal operation in finding the site of the cervix and external os, for the purpose of entering and emptying the uterine blood-sac by this route, so that it has been advised to enter the hematometra at its most prominent point and to make permanent connection between the vaginal canal and the uterine cavity at that point,[33] but this operation yields rather poor permanent results. This difficulty is obviated by immediate laparotomy, as suggested by Pfannenstiel,[19] Halbau,[31] Wertheim, and others.[34]

In view of the fact that a serious condition may develop during the first menstrual period, operation for repair of the abnormality might well be considered before puberty, as recommended by Velpeau.[4] This recommendation has been opposed by various writers. Of course, few cases are likely to come under the surgeon's eye before the first menstrual periods bring the abnormal condition to light and the operation is, as well, a serious one to undertake without immediate indications. However, early operation may prevent grave complications later and may aid in bringing the internal genital organs to

full development, in case they are defective. It must also be borne in mind that nervous symptoms may develop before or after puberty, which are referable to the genital defect and which may often be relieved by repair of the defect. The mucous secretions may collect in low atresia prior to puberty and demand operation for relief at an early date, as in cases cited by Martin.[35]

It is generally stated that the occurrence of a few abnormal menstrual periods leads the patient to seek medical aid and that the damming back of the blood of a few periods is sufficient to cause grave mechanical symptoms. This may be true, for a hematoma of considerable size may form during the first period, but reports of the cases in the present series show that the condition may not become serious enough to bring the patient to a physician until many periods have passed. In 14 cases in which the dates were recorded, the average interval of time between the first menstrual molimena and surgical interference was 2½ years, the shortest interval being 1 month, and the longest, 5 years; nor, contrary to expectation, perhaps, did the cases with the longer intervals invariably show subnormal development of the uterus, indeed, the uterus was quite normal in the case with the 5 years history. In one case the condition had lasted for 20 years after puberty, but here the uterus and one tube and ovary were absent, and vicarious menstruation set in after 6 months of periodic pelvic distress.

It might seem strange that vicarious menstruation does not occur in a greater number of cases, for we find record of few instances. It apparently happens only when the uterus is absent and even in this condition it may not appear at all. In such cases oophorectomy must certainly be considered, although, perhaps, not insisted upon.

The present writers have desired to present the reasons for preferring the immediate use of the abdominal route in operations for the relief of vaginal atresia, coordinating the suggestions of various writers already mentioned, and to urge conservatism in the treatment of the internal genital organs.

Since this was written the patient has menstruated normally and regularly.

HABITUAL CONSTIPATION.*

By DUDLEY ROBERTS, M.D.,

BROOKLYN, N. Y.

VISITING GASTROENTEROLOGIST, BROOKLYN HOSPITAL; GASTROENTEROLOGIST, POLHEMUS MEMEORIAL CLINIC; CONSULTING GASTROENTEROLOGIST, KING'S PARK STATE HOSPITAL.

The prompt and thorough evacuation of the bowels is universally recognized as a fundamental principle in the treatment of disease. The clinician, frequently finding it necessary to make use of this therapeutic principle in the treatment of acute disease, may very readily acquire the habit of permitting or suggesting the use of a daily cathartic for the relief of a constipation which is evidently habitual. Such a tendency may be excused on the ground that for this complaint the public demands laxative drugs, and that the habitual use of the milder laxatives is often harmless and efficacious. In a measure this is true; but this form of palliative therapy would be less commonly called for and allowed were the curability of the complaint more widely and full appreciated. I firmly believe that in a large proportion of instances the causative factor or factors are discoverable and removable; and the results on the general health and comfort of the patient justify whatever time and trouble are required. Practically it may be unwise to urge much investigation or radical treatment of chronic constipation upon those who are perfectly satisfied with the relief obtained from the occasional or daily laxative and with the state of their general health. I am, however, firmly convinced that we should seriously urge the advisability of making attempts at cure when laxatives afford unsatisfactory or gradually failing relief, when fecal stasis is suggested in spite of apparently satisfactory defecations, and when the underlying cause of the constipation is found to be a condition which in itself is detrimental to health and efficiency.

At the outset we must free our minds of the idea that for habitual constipation there is a universal panacea, any therapeutic procedure from which we may hope for success unless it meets the demands of the individual case. It is true that from certain bizarre forms of diet an abnormal fluidity may be given to the stools, or the intestines whipped up to temporarily better action. Carrying such a plan far enough we may be able to secure an actual diarrhea, and such a result is not uncommon from the exaggerated diets sometimes adopted by these sufferers. By a cure, it seems to me, we should understand a restitution of normal bowel movements on a reasonable mode of life and dietetic regimen. Such a cure is only to be accomplished by the accidental or intelligent removal of the conditions responsible for the failure of function.

The phenomena which accomplish the passage of the food residue through the colon and from the body should be separated into two groups or classes. There are really two different mechan-

*Read before the Medical Society of the County of Kings, April 20, 1909.

isms. The movements of the colon down to the sigmoid are reflex in their nature, and entirely beyond the consciousness of the individual. The stimulus to simple contraction arises from the chemical irritation of the intestinal contents upon the mucosa, and the stretching of the viscus by these contents, be they solid, liquid, or gaseous. In this portion of the colon the immediate centers are in the musculature itself. The coördination of contraction and relaxation which we speak of as peristalsis is traceable to centers in the spinal cord. Abnormalities of action may arise as an effect of exaggerated emotional states, the impulses being transmitted through the sympathetic system.

The lower sigmoid and upper rectum is the collecting reservoir of the feces, entirely comparable to the urinary bladder. States of fullness give rise to appropriate sensations, and these to the desire to empty the bowel. The carrying out of this desire is, under normal conditions, subject to conscious control. Without voluntary effort, through the increase of intraabdominal pressure and the relaxation of sphincters it is almost impossible for the rectum to void its contents if these contents are naturally formed. The centers which preside over the musculature of this portion are entirely spinal and under the control of the higher consciousness unless abnormally stimulated.

The clinical study of constipation must involve the determination of the site of failure, that is, which mechanism is at fault, and the reason for the discovered failure. The determination of these facts involves, very often, the most thorough investigation and continued observation. Only in this way may we hope to avoid overlooking the more infrequent morbid lesions the cure of which depends on prompt recognition. The clinical history gives us the leading line of inquiry, and, carefully taken, makes possible a working compromise between ideal completeness and the demands of a busy life. It is not alone to the history of the complaint that we must give painstaking consideration but also to the study of the life and habits of the individual patient in the hope of discovering any possible etiological factors responsible for the complaint.

Other things being equal in the course of physical examination the greatest stress is laid on the study of the condition of the colon itself. This involves the palpation of its separate parts and the study of the position, size, condition, and fullness of these parts. The value of direct examination of the lowermost end of the colon cannot be exaggerated, for through this examination we settle the important question as to the site of stasis.

The examination of the lower bowel is carried out somewhat as follows: The patient is instructed to use no cathartic on a given day, and the following morning to attempt, as usual, to move the bowels. Digital exploration of the rectum is then made and this is followed by a proctoscopic and sigmoidoscopic examination with a proper speculum. If the mechanism of defecation is faulty the rectum or lower sigmoid is found to contain normally soft feces in sufficient quantity. If the trouble is higher up the rectum and lower sigmoid will be practically empty; the character of what is there often gives important indication of the conditions higher up. These examinations inform us as to the cause of any discovered failure of the defecation mechanism, the size of the cavity is estimated, as is the condition of the musculature, the state of the mucosa, and any obstruction from surrounding parts or the muscles of the pelvic floor, including the anus.

The study of the color, form, and consistency of the stools as passed and as removed through the examining tube often gives valuable information. Chemical and microscopical examination of the feces sometimes demonstrates a disease of the upper bowel which otherwise would be overlooked. The time of passage of the feces, carmine having been given with a particular meal, is of great moment in determining fecal stasis.

The study of the gastric contents may be indicated by the clinical history, but need not be made a part of the routine in the study of habitual constipation. While constipation is frequently a complaint in those suffering from gastric disturbances it does not follow that it is due to the alteration of gastric secretion. Other coincident factors are more probably responsible, or possibly, the gastric disease is really due to constipation. This, I believe, is a very frequent occurrence.

Clinically it is convenient to divide cases of habitual constipation into two main groups depending upon the mechanism at fault. Each of these main groups is then divided into types or classes depending upon the apparent predominance of an etiological factor. Such a classification is useful in description and simplifies the practical institution of treatment. No confusion need be caused by the combination of these conditions in the individual case, as appropriate treatment for each may be instituted if required.

1. *Disturbances of Defecation.*—The clinical history of patients afflicted with a failure of the mechanism of defecation is often in itself suggestive. Dietetic cures and alterations in the mode of life have failed to give results unless the stools have thereby been made very soft. The lower bowel at a certain time of day, at least, feels full, but evacuation cannot be accomplished. Enemas, even though small in amount, are effective to a degree. Without such stimulation or softening there is almost absolute inability. Final conclusions are reached through rectal examination both as to the fact of failure here, and the cause of such failure. These causes may be grouped as follows:

Neurotic Types.—In the course of the distinct neurasthenic psychoses constipation may be a prominent complaint and the real causes of such complaints are several. Amongst the actually neurasthenic and those slightly nervous individuals who are in most respects normal the constipation is often due to disturbances of defecation rather than to disturbances of the mechanism above. Defecation is inhibited, the feces are seen to be normal, and the mechanism cannot be said to be faulty. In some cases the inhibition seems to be due to fear or anxiety that the bowels will not move; or that they will not move in the short time allowed before taking up the duties of the day. Sometimes the inhibition resembles the disturbance of micturition such as is observed when the physician asks for a specimen of the urine. Life insurance examiners notice this inability to empty the bladder on request particularly if the applicant is closely watched and therefore excited. Sometimes the inhibition is due to the association of defecation with experience of pain accompanying defecation when the painful condition of the rec-

tum has been cured. An anal muscle which is somewhat tight and must be overcome by considerable effort causes quick discouragement.

Not to attempt an elaboration of this interesting theme at the present time, it may be said that these cases are many and the results of treatment good unless the psychopathy is too pronounced. Whether frankly so or not the treatment is largely suggestive. One may advise a number of simple measures, preferably a routine of measures before defecation is attempted. Habit is very important. In part because of its suggestive value, local rectal treatment, such as gradual anal dilatation, is often serviceable.

Failure of the Muscles of Defecation.—Among women who have borne many children or, for other reasons, suffered great stretching of the abdominal muscles, constipation is often exceedingly obstinate. The trouble is found to be in the mechanism of defecation, in the lack of any assistance in evacuation. Only by proper exercise can these muscles be brought back to their normal state, but the very severe deformities are practically hopeless. I have seen exercises carried out for months with the greatest seriousness but with very little effect. We must be content to keep the feces in as soft a state as necessary on its entrance into the rectum by diet and the like and aid defecation by a tight binder about the abdomen on which the pressure of the depressed diaphragm may be brought to bear, or by having the patient assume the squatting posture during defecation, making the thighs apposed to the belly do the work of the muscles.

Rectal Types.—As a result of continual resistance of the desire of defecation, thus allowing large masses of feces to accumulate in the rectum, the rectum loses its sensibility, and the walls their tone; a large cavity is developed as is shown by the ballooning when the tube is introduced. It sometimes happens that this condition can be traced to the custom of taking large enemas of water while in a sitting posture, a method of treatment of constipation for which a patented apparatus is used. These cases are exceedingly stubborn, but the treatment which gives some chance of success is the establishment of regularity of attempt at defecation, increase of the strength of the accessory muscles, increasing the bulk of the feces by proper diet, and, finally, the lavage of the rectum with small quantities of cold water.

Much the same in effect are the pelvic tumors, uterine displacements, and injuries of the muscles of the perineum from severe labor. These conditions demand surgical relief.

Anal Abnormalities.—Fissures of the anus and hemorrhoids are common causes of constipation, partly because of the pain which they occasion during defecation and partly because of the induced spasm of the anal sphincter which cannot be voluntarily relaxed.

Constricted or spasmodic sphincters without local lesions frequently cause constipation. This is very apt to be observed among the stronger members of society who have no other complaint. It sometimes is possible to trace this abnormality to the habit of resisting the desire to defecate. The individual, possibly a physician, a teacher, or business man rushes off to work after breakfast thinking to move the bowels later in the day. Solids and gases press on the rectum and with much effort the sphincter is gripped hard for hours to avoid unpleasant accidents. The muscles of protection become hypertrophied beyond the power of the expulsive mechanism. The sphincter is found to be broad and thick. These cases are to be cured only by anal stretching, divulsion, or actual division of the fibres by incision. Regularity of habit then prevents a recurrence.

2. *Disturbances of Colon Peristalsis.*—These cases are recognized through proctoscopic examination, the discovery of the empty rectum, and through careful palpation of the colon when cathartics have for a time been interdicted. The rectum may contain a small amount of fecal material and this may indicate whether we have to deal with atony or spasm above. The wall of the sigmoid as high as it can be seen may give useful indications of conditions above. It is a mistake to suppose that in a given case we are dealing either with spasm or atony, for the apparent atony may be due to conditions without the bowel or to failure of stimulation, just as spasm my be due to temporarily excessive irritation. A large proportion of cases that one might be tempted to class as atonic or spastic bowels are bowels which have not reached any definite abnormal state; normal power is there, lacking merely the necessary work to call it into activity, or the necessary stimulation to make it, promptly and efficiently, take up the work offered.

Dietetic Types.—The underfed make up a considerable proportion of the constipated. In large part this class is made up of women. Because of lack of appetite, lack of time or money or real or fancied digestive disturbances these patients eat very little. Sometimes they drink tea excessively, which stimulant they take in place of food. Possibly the tea may be a factor in the constipation; usually this is not the case. These patients are often thin, somewhat anemic and frequently very neurotic. It is natural that the bowels should not move on such a diet as we find, on study, is habitually taken. It is really not the constipation which must be treated, but the starvation. It is very easy to overlook this type, but the results, when treatment is properly carried out, are most gratifying. Even when the constipation is of years' duration good results may be obtained. The course of forced feeding must be insisted upon most firmly and carried out scrupulously. Constipation in enteroptotics is frequently of this type. In another class it cannot be said that an insufficient diet has been ingested but rather that an improper diet is habitually taken. An aversion is felt for all but the most refined foods; all fruits, vegetables, and fats are eaten sparingly. Meat, eggs, well cooked potatoes, and fine breads constitute the entire dietary. They are apt to be better in summer and worse in winter. The normal stimulants are lacking, as is learned from the history, but the diagnosis is settled by making a test by diet. A certain amount of fruit, for example, or agar-agar is ordered and the result watched. The treatment is obvious in principle but in practice often difficult to establish unless the most rigid instructions are given as to the amount and kind of food which should constitute the diet. Schmidt, who first suggested the use of agar-agar, apparently found that it was not efficacious in a sufficiently large proportion of cases, apparently, so that to it he added cascara. I can see no particular reason for elation over the addition of this mixture to the list of cathartics.

Sedentary Types.—The fat and flabby, sedentary, and overfed sometimes suffer from a constipation

due to a faulty colon peristalsis. The constipation may be explained in various ways but personally I have usually found little satisfaction in treating these patients for constipation unless they can be made to recognize the necessity of a fundamental change in their mode of life. Graduated but, finally, moderately hard out-of-door exercise is preferable, but a systematic course of resistance exercises accomplishes good results. The fact of constipation is almost secondary in its importance; the change in habits is demanded by the dangers of the primary condition.

Enteroptotic Types.—Constipation among those with enteroptosis is exceedingly common. Superficially considered it might seem that it was always due to atony of the colon and to angulation at various points. As has been said, however, the constipation is often due to insufficient feeding and on the other hand sometimes to deficient defecation. If the failure is evidently in the colon and there is a severe grade of ptosis it may be justified to consider angulation as a factor. There are cases which do well with a properly fitting abdominal support which otherwise continue to complain of constipation. Main reliance is always to be placed in the improvement of nutrition and the increase of fat by a period of rest in bed, and forced feeding. Complete cure of these cases is obtained only by long-continued adherence to hygienic principles and life in the open air, as the real difficulty is a well developed fundamental disturbance of nutrition.

Colon Atony.—The term atonic constipation should be limited to those cases in which there is evidence that the colon is actually atonic. Such a condition may be due either to essential weakness of the musculature of the bowel or an abnormality of the nervous mechanism resulting in diminished irritability to normal stimulants. The term should be reserved for those cases which fail to respond to the stimulus of a normal food residue. It should be demonstrated that the defect is not in the mechanism of defecation but in the colon peristalsis. I believe that true atonic constipation is far less common than we have been in the habit of thinking. The diagnosis is rarely to be made unless the constipation has been long standing or there has been a recently operative etiological factor, such as a depleting disease or accident. Long-continued and severe catharsis by reducing the normal irritability of the bowel seems sometimes to be responsible for an atony. The positive diagnosis is made through study of the character of the stools, the careful palpation of all parts of the colon, the estimate of its contractility under manipulation, and the study of the upper sigmoid by the aid of the inflating electric sigmoidoscope. Diagnosis sometimes can only be made from long observation. The general treatment of this form of constipation consists in the correction of the mode of life, the proper arrangement of the diet and the betterment of the disturbances of the general health. Locally the attempt is made to improve the nutrition, strength, and irritability of the bowel wall. During treatment it may sometimes be necessary to allow small and diminishing doses of cascara three times daily, before meals. Massage of the colon, if done by someone who can actually palpate the large bowel, is a most useful measure. The professional operators are apparently taught to massage along the course of the bowel and the result is that they do little more than rub the skin. It is of no importance to push contents onward a trifle, but rather we must manipulate the bowel wall directly with the fingers. This can best be done when the fingers are held transversely to the long axis of a given portion so that the segment is rolled under the fingers. I believe this should be done either by the physician or under his immediate instruction. Massage must be kept up for some time if actual results are to be obtained. Oil enemas in some cases work well, and again are of no use whatever. We can best account for this on the supposition that in certain cases irritation results in spasm of certain sections of the bowel too small or too inaccessible to be discovered. In all cases the oil may be of temporary benefit, but in cases in which there is no spasm whatever the effect ceases on discontinuance.

Spastic Types.—Habitual constipation due to spastic contraction of a smaller or larger section of the colon is not at all infrequent. The condition is observed most commonly in the neurotic, in those who have abused cathartic remedies, and in those who have made it a practice to take foods which are irritating to the intestinal mucosa. The exaggerated laxative diet is thus seen to be harmful in a certain proportion of cases. The diagnosis is made by elimination of failure of the mechanism of defecation, the discovery of fecal balls or small calibered stools in the rectum, the history of the passage of such feces, and through the palpation of the colon. It is easy to confuse the spastic bowel, a hard cordlike body the size of the finger, with the normal empty bowel: this is a matter of experience. Many of these patients have pain in various portions of the bowel, and the association between spastic constipation and colica mucosa is close. The recognition and proper treatment of spastic constipation is exceedingly important. Measures useful in other forms of constipation are not beneficial or may even aggravate the trouble; cathartics do not as a rule give even temporary satisfaction. The underlying neurotic conditions are always to be carefully considered and treated more or less radically as indicated, either by psychotherapy, change of environment, or enforced rest. The diet must be made abundant but free from irritants. To this end it is well to use those vegetables which contain large amounts of cellulose, but not fermentable substances, or those which leave a hard residue. Fats are to be taken in as large amounts as can be borne. It is best to start these patients on a strictly milk diet, and after a week change this to a milk and cereal diet, later instituting a full mixed diet, six meals a day, but one that is not irritating.

Oil enemas are of the greatest value. The oil, either a pure olive or sesami, is injected into the rectum and retained over night; the amount of ten ounces is ordered every night for a fortnight and then every other night for an equal time; the further continuance is determined in the individual case. To those who have no one to call upon for assistance in taking these enemas, the enemator devised by me a few years ago is an almost absolute necessity. Aside from the indications of the individual case two drugs are efficacious in treatment. I refer to liberal doses of bromide and adequate doses of atropine. Combined with other treatment, these two are of great service in relieving part of the discomfort at the outset.

Catarrhal Cases.—While it is not within the province of this paper to discuss catarrhal inflammation of the bowel, in view of the frequency with

which the chronic form supervenes upon long continued constipation and the use of purgatives it is necessary to make more than passing mention of it. Contrary to what is frequently supposed, such a form of chronic catarrh causes or keeps up a chronic constipation, chronic diarrhea being the exceptional phenomenon unless there is ulceration of the bowel. Those afflicted with catarrh usually suffer much from intestinal flatus and irregular pains along the course of the colon, referred to other organs. Sigmoidoscopy may give an indication of the catarrh above. The stools show mucus in varying amounts. The diet in these cases must be full and unirritating, very much the same as for the spastic form of constipation, to which the catarrh frequently leads. Massage is of value when there is no developed spasm. Intestinal lavage is of far more value in these cases, in my experience, than enemata of oil.

The brief presentation of such an important subject as this lays one open to criticism. Certain aspects of the subject have necessarily been omitted or mentioned too briefly. The treatment of the subject has been suggestive and synoptic throughout. Particular stress has purposely been laid on the classification of cases and the clinical points which from personal experience seem to me most useful in the recognition of these different classes. If we fully appreciate the diversity of causes of constipation we are less apt to expect a panacea and we are more apt to realize that failure in treatment is due to failure in diagnosis. I doubt that the future holds much in the way of new therapeutic procedures in the treatment of this complaint, but I believe that success will be expected through the insistent application of present therapeutic principles in accurately selected cases.

SCIENCE AND MEDICINE WITH SPECIAL REFERENCE TO THE TREATMENT OF SYPHILIS AND GONORRHEA.

By F. BAUMANN, PH.D. (KOENIGSBERG), M.D.,

CHICAGO, ILL.

The vital activity of every cell of the animal as well as of the vegetable kingdom stands of necessity in a certain relation to the outside world. The exact nature of the stimulus which causes the cell to grow and to regenerate is not known, but it can be shown experimentally that every change in the condition of its surrounding is an interference, an injury which causes a depression of the vital activity. The depression may under certain conditions be followed by a period of increased vital activity. Even if we take the point of view that nature's actions are without purpose, still only those organisms can exist that adapt themselves to the surroundings; the mere fact, therefore, that an organism is still in possession of the battlefield after millions of years of fighting for existence shows that it has a rational internal organization and compels our mind to look upon any change which it, as a result of an interference, undergoes as a rational endeavor on the part of living cells to adapt themselves to the changed condition of life by a defensive reaction. It is, therefore, entirely within the limits of logical reasoning, if we pronounce the clinical picture of a disease as we see it at the bedside or of an animal experimented upon with drugs, as we see it in our laboratories as an adaptation of an experienced fighter to the changed surrounding, as a rational physiological action of self-defense.

The internal or primary effect of a change in the surroundings is always the same, but the outward manifestation, the clinical symptoms, varies according to the gravity of the interference. As an experimental fact of the above said, I will mention the negative phase of phagocytosis following the vaccination with dead microorganisms. The negative phase may vary in length and severity, but it is always present and represents the primary effect of the interference. A positive phase of phagocytosis will follow this injury, if the individual has enough vitality to react properly, to respond by a defensive reaction. On the other hand, it would be erroneous to conclude, as is occasionally done, that vaccination depresses phagocytosis only. On the contrary, this therapeutic interference depresses the whole vital mechanism of the body, but the phagocytic index is the only part of the injury which can easily be ascertained and graphically demonstrated.

Furthermore, in some of the most infectious diseases, such as Asiatic cholera and chicken cholera, phagocytosis does not constitute an essential part of the protective and immunizing forces of the body.

The nature of the secondary or outward effect, the reaction to a dose of medicine or to a vaccination, or to an attack of an infection depends upon the relative size of the injury. An interference which lies within the recuperative power of the individual will to all outward appearances act as a stimulant; it will increase the vital activity; while an interference that oversteps the above-mentioned limits will to all outward appearances depress or even destroy the vital activities and result in death.

The direct effect of light, heat, and all chemically active substances (drugs) consists in a depression of the vital activities, but as long as the relative size of their doses does not overstep certain well-defined limits, the resulting secondary or apparent effect will be an increase in the vital activities.

To explain the above on a practical example, it may be mentioned that bichloride of mercury, regarded as one of our most deadly poisons and germicides, becomes a stimulant to cellular activities as soon as its watery dilution is greater than 1:400,000 to 1:500,000. That is, the addition of this solution to a culture of microorganisms makes them grow more luxuriantly than the control culture to which bichloride of mercury has not been added.

The optimum dilution varies somewhat for the different kind of microorganisms.

It would not be difficult to show that such relation exists between the living cell, and every chemically active substance. It may be well to mention the relation of a few of the most common drugs: iodine becomes a stimulant or a tonic to cellular activity in a watery dilution of 1:600,000; potassium iodide in a watery solution of 1:100,000, and salicylic acid in 1:4,000.

The chemistry of the organic compounds taking part in the vital processes of the human body is still in its infancy. Of the multitude of organic bodies, which probably play a more or less important rôle in the vital economics, a few only are known, and even of those there is no one whose action is definitely known, as yet. But all of these experiments show one thing of the greatest importance for the physician, namely, the fact that the primary action of any drug and of any vaccination is an injury. To be sure, it can be specific in so

far as certain drugs or certain toxins show preference for certain kinds of functionating tissue, but it is very doubtful if any drug or any toxin has otherwise truly qualitative action.

Our materia medica, therefore, misrepresents the true relation of the living cell, and with it of the human body to the outside world. Science does not know of any directly curative drugs, and cannot find any justification for the generally accepted division of the drugs into tonics, poisons, etc., etc., and it does not support the view that the same drug differs in its primary action on the human system, according to the size of the dose.

Such teaching is not only faulty and suited to prevent scientific progress, but it also tends to mislead the medical student and impair his judgment. It is due to thus misguided clinicians that many widely advertised preparations, which consist for the most part of chemically inert compounds, have been introduced in the practice of medicine, though their own manufacturers' statements say that they can be used on the infected mucous membrane in solutions of 1 to 25 per cent. strength without causing pain or irritation. A drug, in order to act as an antiseptic, must be in a chemically active state. But the application of a chemically active substance to the infected mucous membrane produces an irritation, and is followed by a transitory increase in the clinical symptoms consisting of pain, swelling, and discharge of pus.

The above holds true, in fact for the action of any effective therapeutic interference, and shows that the action of the drug and that of the disease are in the main the same; but the drug can be given in measured doses, while the infection, once started, is beyond our control.

In the clinical picture of gonorrhea, as well as in that of syphilis, is represented the defense of a highly specialized cellular state against an invading unicellular microorganism, or, speaking from the point of view of the intruder, it represents an attack of a unicellular organism on a complicated (complex) cellular system.

The physician is appealed to to devise means whose aim it is to help the human body to combat and ultimately remove the pathogenic germ. But as the physician's effort to guide the course of this struggle is limited to the production of injuries, and as the injury intended for the disease-producing germ will equally affect its host, the therapeutic results, good or bad, will depend upon the resistance and recuperative power of the patient, on the one hand, and perhaps to a lesser degree upon the virulence and vegetative properties of the germ, on the other hand. It follows, therefore, that the treatment of any infectious disease is but an experiment which has to be repeated, and presents itself in a different form with every new case.

In experimenting with animate matter, we have always to remember that every interference on our part will be followed by a defensive reaction, which, though purely physiological, can easily be mistaken for a pathological change. Such mistakes are frequently made, and often found in medical literature, and they constitute one of the main obstacles to the introduction and use of rational thought in medicine.

Clinical experience has shown mercury and iodine to be the best drugs with which to influence the course of syphilis, but they are probably not any more specific or tonic for syphilis than they are for gonorrhea, because their usefulness in the former disease depends mainly on physical rather than on chemical properties.

1. Mercury is in a liquid state at room and body temperature, and can therefore easily be divided into small particles and absorbed and converted into salts, which are capable of dissociation.

2. The dissociation of the salts of mercury is very small even in solutions of great dilutions. They, therefore, spend less of their chemical energy and cause less of a reaction locally than the more readily ionized salts of silver and copper. The chemical force of the latter salts is almost entirely spent locally the instant their solution comes in contact with living tissue. The salts of iodine, too, are distinct by the low percentage of dissociation.

3. The albuminates of mercury formed by the contact of its salts with protein substances are relatively easily soluble in an excess of protein substances, and can in this form be carried by the blood current throughout the body.

The action of mercury is an injury to the patient affected with syphilis as well as to the healthy person; in fact, the dose of mercury which lies within the recuperative power of an individual is larger in health than in disease. The administration of mercury will give beneficial results so long only as the injury to the syphilitic germ is greater than to the tissues of the patient. It is, therefore, at once apparent that hygienic measures are of the greatest importance in the treatment of syphilis, not only with reference to the ultimate cure, but also with reference to the dose of the drug that can be given with beneficial results.

The therapeutic dose of mercury is larger for the same individual if it is kept in a state of high vitality than otherwise, and the microorganisms neither multiply as rapidly nor do they become as virulent if forced to grow on tissue of high vitality as would be the case if the culture media were better suited for their growth. Cases of syphilis with long intervals between the infection and the appearance of the secondary rash are usually of mild nature, because the soil is apparently unsuitable for rapid growth, and it takes a long time before the detrimental effect is felt by the body as a whole to such an extent as to arouse the defensive mechanism of the whole system.

It has happened to me a number of times that luetic patients having changed their work from outside to inside would get salivated on the same dose of medicine which was taken with impunity in their former occupations.

It seems that the human system has in any given state of health only a certain well-limited amount of energy with which to perform its functions, consisting in building up, defending, repairing and reproduction, etc., and that by relieving the body of some of its work more energy will be at the disposal of defense and repair. A patient, therefore, who is kept in bed will for the time being tolerate larger doses of mercury and iodine than when up and at work, provided all other conditions are equal.

The reason why antisyphilitic treatment does not, as a general rule, give as favorable results in cases of long standing as in newly infected persons has variously been ascribed to the increased tolerance of the syphilitic germ toward mercury, but from our point of view it is much more likely that the vitality of the old patient is lower than that of the newly infected, and does, therefore, not properly respond to the additional injury produced by the administration of mercury or iodine. This corresponds also

with the fact that some such cases do well under good sanitary and hygienic conditions, and without the help of any medical treatment.

In gonorrhea we deal with a more or less localized infection, but the general laws mentioned in the treatment of syphilis will also apply here. A patient kept under good sanitary and hygienic conditions will tolerate larger doses of urinary antiseptics internally and stronger irrigations and injections locally, and the injuries produced by the treatment will heal quicker, and can be repeated within shorter intervals than in individuals of low vitality.

In the internal treatment of gonorrhea we use drugs that are excreted by the kidneys in a chemically active form and dissolved in the urine act as antiseptics to the infected part of the genito-urinary tract; in order to get some useful injury into the infected part of the genitourinary tract, we are compelled to do harm to the whole human mechanism.

Internal treatment is indicated for short periods of time in strong, healthy individuals, especially in those living an outdoor life, and in acute infections, but it is contraindicated in sickly individuals living an indoor life, and in chronic cases. In individuals of low vitality the internal treatment is always of questionable value, and should be replaced as soon as possible by local treatment. I have never been able to demonstrate with the urethroscope the absorption of chronic gonorrheal infiltrations by internal medicine alone, and do therefore not believe that any permanent improvement can be obtained by such treatment alone.

In local treatment we try to interfere with the growth and the spread of the gonococcus by the direct application of chemically active substances, and by the use of dilating instruments in the inflamed parts of the genitourinary tract.

In this method of treatment the injury to the human body as a whole is reduced to a minimum; it consists in an increased absorption of the toxins produced by the attacking germ. Since this injury is our more effective means to stimulate the human system to an increased effort at the defense, we must regard it as useful and necessary.

The absorption of toxins of the infecting microorganism is an essential part of the rational therapeutics of gonorrhea.

The antiseptic substances used for irrigations and injections come in contact with the germs of the surface of the mucous membrane only, and not with those hidden in the glandular structures. The urethral membrane is very richly supplied with glandular structures. Lichtenberg* found about 20,000 to the square inch. These structures are the most favorable breeding places, because the specialized cells of the glands are not only an easier prey and better soil for the gonococcus than the epithelium of the surface of the mucous membrane, whose function is protection, but the situation, too, makes it difficult to bring the glandular cells therapeutic aid. The action of the therapeutic agents with reference to the glandular cells is an indirect one only. It consists in the production of an increased hyperemia. The word hyperemia is used here in the sense of Bier and his school. It is a collective expression for the sum of means which the human body uses to fight an invader.

The question as to the kind of chemically active substances that should be recommended for use in the treatment of gonorrhea can be answered in a general way only:

1. The drugs in question should be of simple and definite chemical formula. Such drugs are: Nitric acid, sulphuric acid, phosphoric acid, peroxide of hydrogen, permanganate of potassium, sulphate of zinc, sulphate of copper, and nitrate of silver.

2. In the treatment of acute inflammations, preference must be given to drugs whose chemical activity consists mainly in oxidation, such as acids and salts with cation of small toxicity, such as potassium permanganate and zinc sulphate, because these are more cleansing and their injuries on the mucous membrane repair quicker than the salts with cation of great toxicity, such as copper sulphate and silver nitrate. The latter are indicated in the more chronic inflammations, but they should not be applied any oftener than every four to five days, since their injuries take about that length of time for repair. For more specific information concerning the chemistry of the antiseptics see my books on Gonorrhea (Appleton & Co., New York, 1909).

3. The physician should limit himself to a small number of drugs, in the use of which he has become expert.

4. The physician should always keep in mind that the success of his treatment is much less dependent upon the kind of drugs he uses than it is upon the intelligent use of any given drug. A thorough acquaintance with the pathology of the disease he treats and the chemistry of the drugs he uses will insure the results of his treatment.

The instrumental treatment endeavors by graduated dilation to soften and break down the pathological tissue, and to allow a freer exit for the pent-up pus. The indirect action of the dilatation is essentially the same as that of the antiseptics; it consists in the production of an injury and a specific intoxication of the host, but the damage done by a dilating instrument repairs slowly—four days to four weeks may be given as the time required for complete healing.

The urethra is a channel of very uneven caliber, the narrowest part of which is normally located at or near the meatus. The therapeutic action of the sounds and bougies is therefore practically limited to the first inch or two of the urethra, and only very prominent pathological lesions located in other parts of the canal can be treated and partly absorbed by these instruments. Frequently, I may say, it is the rule to find in old cases of gonorrhea with obstinate course urethral enlargements measuring 62 Char., and more. Those pockets cannot be treated with the sound or the bougie, but their infiltrations yield readily to dilators adapted to their shape.

To repeat, then, in order to treat gonorrhea rationally, there is needed a thorough knowledge of the chemical and therapeutical action of at least one oxidizing and one astringent drug, and the procession of instruments capable of dilating to the limit of its elasticity any part of the urethra.

It may be mentioned that five cases of gonorrhea complicated by rheumatic pains affecting various parts of the body, which had been treated by the above described method, and in which the rheumatism did not disappear during the course of the treatment, were subjected to gonorrheal vaccine treatment, but the results were all negative.

If I should be allowed, then, to draw conclusions from this limited experience, I would say that the most promising cases for vaccine therapy are those which have been treated by antiseptics and instruments in an irrational and inadequate way only.

THE CAMPAIGN AGAINST THE HOUSE-FLY.

IT is never an easy matter to convince human beings that that with which they are familiar and have long considered harmless, may in fact be a source of danger to health, and it is even more difficult to persuade them so to change their mode of life as to eliminate the danger. No better example of this exists than the contempt in which the common house-fly is held, and the laugh which is apt to follow any suggestion that this insect is more than a disagreeable companion. This is so, too, even after it has been proven beyond question that this familiar pest is a common means of transferring typhoid fever from man to man, and is thought by some to be the chief cause of infection of infants with summer diarrhea. Even if we had no records of local epidemics of typhoid fever unquestionably due to the house-fly, if we had not cultivated the typhoid bacilli from fresh fly specks, and had not seen the effect on the bacterial contents of milk due to exposure to the insects, we would have but to call to mind the scenes of a country farmhouse, the dining room, kitchen, dairy, manure pile, and privy vault, all close together, and to remember the familiar buzz which greets our ears on entering each in turn on any summer day, to be convinced of the ease with which disease may be contracted through the agency of these pests. At meal times the flies are in the kitchen and dining room; between meals they are in the manure pile and the midden. The thought is not pleasant.

Granting then that flies may be the cause of the spread of disease, what steps have been taken in the past and what are being taken at present to overcome the danger? In 1895 Kober, the Health Officer of Washington, in his annual report mentioned casually that a few small local epidemics of typhoid fever in the suburbs might be due to open ditches and flies, and advised that such places be cleaned up. The next year, his successor, Woodward, investigated the stables in a limited area and enforced regulations which reduced the number of flies markedly. In 1897, in Utica, N. Y., Wallace Clarke, the newly appointed Health Officer, began what was probably the first systematic sanitary crusade against the fly. Noting that sixty per cent. of the cases of contagious diseases in his city occurred in one ward, a ward especially open and sparsely populated, and investigating the reason for this, he found that the refuse from the city was dumped on a farm in the outskirts of this ward; that there the ground was covered, not only with garbage but with the output of the privy vaults; that it swarmed with flies, and that with the prevailing summer winds these were driven in hordes into the city and settled in this particular ward. Against severe political opposition a garbage and night soil reduction plant was obtained, the dumping ground was abandoned, and the number of contagious disease cases in the infected ward dropped to its normal ratio. Clarke then commenced a fight against privy vaults, but was soon retired from his position, and we note that the present Health Officer reports that they "have never made any investigation in regard to the transmission of typhoid and other germs through the medium of the house-fly."

During the Spanish-American and Boer Wars much was said concerning flies in camp causing the spread of typhoid fever and dysentery, and some, for the most part ineffectual, measures were taken to prevent it. After this general interest seems to have waned, and except for a few scattered reports but little was done until Nash, in Southend-on-Sea, in England, showed that by cleaning up the refuse piles in his locality, both flies and cases of infantile diarrhea became rarities. Nash, too, after rendering Southend a model town from a sanitary viewpoint, fell under the political axe and was retired.

As a result, however, of the work of these, and a few other enthusiasts, who are only now becoming recognized as progressive sanitarians, and not as cranks, the belief in the dangers of the fly as a mode of contagion has slowly gained more and more adherents. The disciples have been scattered, and their work local, and it has remained for a lay organization, The Merchants' Association of New York, to start a general campaign against this insect. Two years ago their committee investigated the conditions of the waterfront of New York, discovered its filthy condition, and showed how the filth was carried to food by the feet of the flies, causing the prevalence of summer diarrhea and the fall rise in typhoid fever in these neighborhoods. This organization has lately taken a second step in its crusade, by the publication of another pamphlet, "The House Fly at the Bar: Indictment: Guilty or Not Guilty?" In this valuable pamphlet appear the opinions of sanitarians from all parts of the United States and Canada on the work of the fly in spreading contagion. A large amount of evidence is collected to show that both typhoid fever and diarrhea are transmitted by flies, and finally the pamphlet considers the best method of protection against this source of danger.

The subject of the defence against fly contagion divides itself naturally under three heads: the protection of the fly against infection: the destruction of the fly; and the protection of man against the fly. Any one of these, if perfectly attained would bring about the desired results, but, as perfection in such things is well-nigh impossible, an effort must be made to accomplish all three simultaneously.

The fly is protected against infection, first, by keeping him away from the invalid. Sick rooms and hospitals should be carefully screened, and every fly found inside be immediately killed. The excreta of typhoid, dysentery, and diarrhea patients should be thoroughly and immediately disinfected. Human excreta from both the healthy and the ill should be deposited only in the proper receptacles, and, if these be privy vaults, they should be kept disinfected and tightly screened. The destruction of the fly, at first thought a hopeless undertaking, is, when the habits of the insects are considered, not impossible. The house-fly breeds almost entirely in manure, the larvæ hatching out in from ten days to two weeks. The first step then is the destruction of these breeding places. To each stable should be attached a waterproof, smooth walled, tightly covered bin, in which all manure should be placed promptly, and which should be cleaned out every seven days. The streets should be cleaned at least twice a week, and all manure carried through them in tightly closed wagons. These same rules apply also to the care of human excreta, garbage, dead animals, and organic filth of all kinds. If these were kept covered and removed weekly, the flies would soon disappear. The third factor, the protection of man against the fly, lies largely in the care of food stuffs, which consists essentially in careful screening. This is especially true with milk, that ideal culture medium for bacteria. The cow shed and the dairy should both be protected, and the milk pans tightly covered. At the store milk must be covered and the edibles put on display carefully screened, a procedure now required by law in Philadelphia. Again in the home, the kitchen, pantry, and dining-room should be made as nearly as possible fly-proof by careful screening, and the food kept covered in summer time. The expense of screening need not be great, as where wire screens are not to be had or the expense of putting them on all windows and doors is too heavy, cotton mosquito netting is a cheap and satisfactory substitute.

The work of the Merchants' Association of New York in spreading this knowledge broadcast cannot be too strongly commended. The Health Commissioner of Chicago, a progressive sanitarian and energetic guardian of the health of the community, has also just issued a leaflet for general distribution in which attention is called in text and picture to the fly as a public enemy. It is such work as that of the Merchants' Association in this city and of the Health Officer in Chicago that attracts the attention of the masses, and makes great reforms possible. It is to be hoped that the effort will be appreciated by other health authorities, legislators, and private citizens and that the results will be a more careful study of fly contagion, and an organized campaign against this insect, the barometer of the filth of the community.

VITAL STATISTICS IN GREAT BRITAIN.

A SERIES of figures and charts, treating of public health and social conditions in Great Britain has been collected recently by the Local Government Board and issued in the form of a Blue Book. The volume is extremely instructive and illustrates in a clear manner such subjects as the growth of population, mortality, public health, occupations, periods of industrial prosperity and depression, pauperism, development of education and of thrift. It may be of interest to learn, if only for the sake of comparison, some of the facts tabulated in this book.

In the middle of 1908 the population of the United Kingdom was in the neighborhood of forty-five millions. Since the year 1851 the population of England and Wales has nearly doubled, that of Scotland has increased by 67 per cent., and that of Ireland has decreased by 33 per cent. The natural increase of population, that is, the difference between the number of births and the number of deaths occurring in any given period, has considerably declined during recent years. As a matter of fact, the death rate has decreased in thirty years from 22 to 15, and during the past three years the birth rate has gone down rapidly. One of the chief causes of the progressively retrograding birth rate is that persons in Great Britain do not marry as they did formerly. In 1850 the number of married persons was 17.2 for every 1,000 inhabitants, while in 1909 it had declined to 15.8. Of course, a very striking feature in statistics relating to population in civilized countries has been the tendency during the past half century of the population to concentrate in cities, and in England this is especially marked. In 1881 the population of urban areas was 68 per cent. of the aggregate population; in 1901 the population of urban districts was 77 per cent. of the aggregate population.

The birth rate of Great Britain has gone down, but the death rate has so greatly declined that the increase of population is still large. Indeed, the saving of child life in England in the course of the past few years has been most gratifying, and shows that rational measures in this direction can effect much.

The most generally interesting portion of the volume under discussion is that which deals with comparison of the mortality in various occupations. Taking 1,000 as the central mean, the proportional liability to death of males between the ages of 25 and 65 is, according to their occupation, as follows: Clergymen, priests, and ministers, 524; gardeners, 563; gamekeepers, 586; farmers, 596; engine drivers and stokers (that is to say, locomotive engineers and firemen), 610; farm laborers, 621. The most unhealthy occupations are those of copper miners, 1668; saloon keepers and spirit dealers, 1781; hotel servants, 1883; tin miners, 2131; general laborers, 2235. These tables also appear to demonstrate in the most convincing manner that work is beneficial to health and tends to longevity, for they show that the liability to death among occupied persons is 1,004, while that of unoccupied males is 2,566. From a careful examination of the causes of death during a period of 30 years, it is shown that the mortality from most of the principal diseases has declined in that time, the chief exceptions being pneumonia, diphtheria, and cancer.

How greatly housing conditions have improved in England and Wales is evidenced by the follow-

ing figures: In 1891, 640,410 one-room tenements existed in England and Wales, excluding London; in 1901 the number had been reduced to 507,763. Three million and forty-four people lived in overcrowded tenements and this had been reduced to two million, six hundred and sixty-seven thousand, five hundred and six, again excluding London. In London, in 1891, 387,156 one-room tenements existed, in 1901 there were only 304,874; 831,668 persons lived in overcrowded tenements; there are now only 726,096.

Statistics with regard to the above subjects would be difficult, if not impossible to collect from America as a whole. But enough is known of the matter to state that considering the difference of climate and of conditions of life, they would not vary much from those of the British Blue Book. Child life is perhaps better cared for in Great Britain than throughout this country, but the general health of the population in America is better than in the United Kingdom, owing to the greater trend of population to cities in the latter country. In this land a similar tendency is evincing itself, but not as yet to the extent it has shown in England. The publication of statistics such as quoted is productive of much good, and their importance is not confined to the country in which they are issued. They provide food for reflection in all civilized countries.

Education of Defectives.

A subject which has taken on a large degree of importance in these days of the systematic examination of school children is the education of defectives. In every public school there are a number of children who are presented to the medical inspector as defective mentally in some way. The question which is presented for solution is what are we to do with these boys and girls who are not learning anything under the ordinary school system, who become habitual truants and later enter the ranks of the insane, the suicide, the criminal. Nearly all of these children possess a certain amount of ability in some line, often a manual one. Could they be properly taught they might be a benefit to the community instead of a burden and an injury; but as yet we lack a system of education for such defectives. Decroly in *La Policlinique* for March and April, 1909, states his belief that the family physician may do much toward the solution of this problem, and that he should exert his influence in every direction, in medical congresses and other meetings, and on educational boards, in the direction of obtaining development in manual lines for those children incapable of development in an intellectual direction. We should bear in mind that education should develop the faculties of action and the ability to apply these faculties in a useful manner, and to get results in the line of work, and in useful lives. There are three agencies in which the physician may work—the family, the school, and the social organization. The parents must be educated in the prevention of errors of hygiene and mental education. They must be taught a rational physiology and a knowledge of the intellectual and moral deficiencies of children. In the school the physician may aid in developing medical school inspection in the line of education, instead of in the prevention only of contagious diseases. He may aid in establishing a type of schools for manual training of those that cannot learn in an ordinary way. These children make good artificers in various directions. Manual and farm schools will help to solve this problem. These children, equally with the blind and the deaf, should be taken charge of by the State in properly governed institutions. Again the physician may aid in getting children's courts, in preventing the imprisonment of children less than sixteen years of age, and in creating clinics especially for school-children, where they can receive treatment and guidance in hygiene. In all of these directions the State should recognize the value of the services that can be rendered to it by physicians, and should be willing to compensate them for the time that must be spent in developing such a system of education.

Meat Poisoning.

The fact that various diseases can be contracted from eating the flesh of the lower animals when it is itself diseased or spoiled has been known for many centuries and many laws, religious, civil, and medical, have been enacted to regulate the sale of meat. This is especially true in Germany, where the more extensive eating of raw meat has made the danger greater and in consequence the need of stringent slaughter-house and inspection laws more positive. In an article in the *Deutsche medizinische Wochenschrift* for May, 1909, Schneidenmühl of Kiel, after discussing the various infectious and parasitic diseases transmitted through the flesh of cattle, divides cases of meat poisoning into three classes. To the first class belong those diseases contracted by eating meat from animals themselves diseased, usually suffering from a definite bacillary infection. The danger of this class lies in the fact that cooking does not destroy the poison. The symptoms appear quickly and are those of an acute gastroenteritis. Cases in the second class, the so-called sausage poisoning, occur after eating raw sausage and other meats which have been improperly stored and stacked in unhygienic cellars. The symptoms come on later than in the first group, after from twelve to twenty-four hours' incubation. They are vomiting and constipation, with disturbances of vision, speech, and swallowing. There is no fever. Cooking renders the meat safe. The third class comprises the "chopped meat poisoning" cases. This disease is caused by contamination during the process of chopping. It occurs only when the meat has been prepared in very hot weather, and is eaten raw. The symptoms are vomiting, diarrhea, headache, dizziness, etc. It is rarely fatal. Schneidenmühl says that the knowledge of the average medical man of these forms of disease is very meagre, and he urges an increase in the number of chairs in comparative pathology in the medical schools.

A New Symptom Complex.

Every few years to the joy of the medical curiosity collector and the confusion of the student, an addition is made to medical literature and terminology by the description of a new disease. It is now several years since the Hollanders called attention to the enterogenous cyanoses and Osler brought forward polycythemia, and the time is quite ripe for something new. It is not surprising, therefore, to find in the *Münchener medizinische Wochenschrift*

for June 1, 1909, an article by Fleischer of Tübingen reporting two cases and collecting two more to make up material for a new symptom complex. In all four of these cases there were marked symptoms of organic nervous disease, three having been diagnosed as multiple sclerosis and one as pseudosclerosis. The characteristic point about all was a definite brownish green pigmentation of the cornea. All the cases occurred in men between twenty and thirty years of age. Two had glycosuria, one permanent, the other transient. The other symptoms were enlarged spleen and enlarged cirrhotic liver. There was in one case pigmentation of the face. The nervous symptoms consisted of marked intentional tremor without the scanning speech or nystagmus of true multiple sclerosis. It will be seen that these cases combine symptoms of multiple sclerosis and bronzed diabetes. Two cases which came to autopsy, however, failed to show the lesion of either. The pigment in the cornea was shown to be hemosiderin. At one autopsy this same pigment was found deposited in various organs. These cases certainly would give the impression of belonging together, and probably to a new class of disease. If it prove to be a new symptom complex, it is to be hoped that it will bear the name neither of Kayser, to whom belongs the credit of reporting the first case, nor of Fleischer, who describes it as a definite disease, but that it will be given a name in some way descriptive of the condition.

News of the Week.

The Death Rate in New York City.—The city's death roll last week was 1,234, an increase of 94 over the corresponding week of last year, but with a smaller death rate, increase in population being considered, than for the same week last year. Deaths of children under 1 year last week were 222, as against 268 for last year; there were 372 deaths of children between 2 and 5 years, as against 399 for the same period last year. There were 546 deaths in tenements last week, as against 473 for the same week last year, and 21 from scarlet fever, as against 28 last year. Despite the increase in population, the deaths from tuberculosis were only two more than for the same week last year—145 to 143. The week's death rate was 14.10 per thousand, against 14.45 for the same week in 1908.

Deaths from the Heat.—Thirty-two deaths from heat prostration occurred in this city last week, according to the mortality report of the Health Department. During the corresponding week last year there were five deaths from the same cause.

Convalescent Home for Infants.—The Chappaqua Convalescent Home was opened in Westchester County, N. Y., on June 28. It stands on the slope of Chappaqua Mountain and has seventy acres of ground. The hospital has a capacity of two hundred and will be open the year round for the treatment of crippled and sick children. There is no time limit for the patients. When necessary the mothers of the patients will also be cared for. The institution was made possible by a gift of $500,000 by Mrs. A. A. Anderson a year ago.

Combination to Help the Infants.—The Health Department of New York City has published a list of sixty-eight public and private institutions engaged in summer health work. These various establishments are contributing funds, nurses, doctors, milk, fresh air relief, and medical or hospital care, according to the nature of the society or institution. The workers expect that still better results will be shown in a decreased death rate before the end of the summer.

Day Camp for Tuberculous Children.—The establishment within the city of Chicago of a day camp for children predisposed to tuberculosis was discussed at a recent meeting of the Board of Directors of the Chicago Tuberculosis Institute and a committee was appointed to work out the details of such a camp.

The Antinoise Society and the School Children.—Mr. William H. Maxwell, City Superintendent of Schools, has written to the principals a letter to be read to the children asking them in the vacation about to begin to refrain from making any noise near a hospital or near any house where they know there is any one sick, and especially not to explode any fireworks near a hospital on the Fourth of July.

Radium.—The largest single order of radium ever given was placed in London recently by Lord Iveagh and Sir Ernest Cassel, who will donate it to the Radium Institute. The quantity ordered was 7.5 grams and the price was £30,000. The Red Cross Guild Hospital of San Mateo, California, has received a gift of radium from Mrs. Whitelaw Reid.

Yellow Fever has made its appearance in Vera Cruz, Mexico.

Wood Alcohol Poisoning.—Two cases of wood alcohol poisoning occurred in New York City (Williamsburg) within a few minutes of each other recently. One was fatal, the other recovered. Both men had been served at the same bar, the proprietor of which was promptly arrested.

Cocaine Seller.—In New York, recently, a man who pleaded guilty of selling cocaine was sentenced to a year in the penitentiary.

Drug Selling.—The pharmaceutical board of Utah will, in the next few days, start a warfare against the violations of the statute regarding the sale of dangerous and poisonous drugs. Especial attention will be devoted to the sale of dangerous drugs by the "corner stores" of country towns, where stocks of general merchandise are sold.

A New Journal has appeared under the title of *The Journal of Pharmacology and Experimental Therapeutics*. The editor is Dr. John J. Abel, of Johns Hopkins University, in association with a number of other experimenters, and in collaboration with the members of the Society of Pharmacology and Experimental Therapeutics.

The Franklin (N. H.) Hospital Association has recently acquired the Aiken homestead. The house will be converted into a public hospital.

Toronto Hospital for Incurables.—On June 17 the cornerstones were laid for two new buildings. Sir James Whitney, Prime Minister of Ontario, performed the ceremony for the new hospital wing and Lady Mortimer Clark for the nurses' home.

University Appointments.—Dr. William D. Hall, of Montgomery, Ala., until a year ago a member of the medical faculty, has been appointed Acting Vice-Chancellor of the University of the South.

Dr. John A. Tipton, of Carroll County, Virginia, has been made a life member of the Board of Visitors of the Medical College of Virginia.

The New York University and Bellevue Hospital Medical Society has acquired three houses on

First avenue and Twenty-fifth street, adjoining its present buildings, and will erect an addition to the school on the ground occupied by them.

Honorary Degrees conferred upon medical men during the past week include that of D.Sc. from Cambridge University to Dr. Jacques Loeb of the University of California; LL.D. from Williams College to Dr. Wilford T. Grenfell, surgeon missionary in Labrador, and D.Sc. from Colgate University on Dr. J. I. Hefferen of Syracuse University.

An American Knighted.—Sir Francis J. Campbell who received his knighthood last week at the hands of King Edward was a native of Tennessee. Blind from early childhood he devoted his life to the treatment and training of the blind in London with such success that this honor, so rarely given to one of foreign birth, has been bestowed upon him.

Hospital Appointments.—Dr. Freeman A. Tower of Worcester has been appointed superintendent of the Burbank Hospital at Fitchburg, Mass.

Dr. Henry Lloyd of St. Louis has become assistant superintendent of the State Hospital for the Insane at Farmington, Mo.

Dr. John Howland has been appointed Assistant Attending Physician to Bellevue Hospital, in charge of the P. and S. division of the Department of Children's Diseases, and Dr. Herbert B. Wilcox, Adjunct Assistant Attending Physician in the same department.

Illinois State Board of Health Examinations.—Written examinations were held in Chicago, January 18, 19, and 20, by the Illinois State Board of Health, and, according to the report of the secretary, Dr. James A. Egan, the number of subjects examined in was 16; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined, 45, of whom 21 passed and 23 failed. One candidate took an incomplete examination.

The Kansas State Board of Medical Examiners has elected Dr. H. A. Dykes of Lebanon, Kan., *President*, and F. P. Hatfield of Olathe, *Secretary*.

The Medical Society of New Jersey, at the annual meeting at Cape May, on June 24, elected the following officers: *President*, Dr. B. A. Waddington of Salem; *Vice-Presidents*, Drs. Thomas H. MacKenzie of Trenton, Daniel Stroch of Camden, and Norton T. Wilson of Elizabeth; *Corresponding Secretary*, Dr. Harry A. Stout of Wenona; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Moyer of Newark; *Councillors*, Drs. Thomas W. Harvey of Orange, Edward F. Denner of Paterson, William A. Clark of Trenton, William H. Izzard of Camden, and James Hunter of Westville; *Delegates to the American Medical Association*, Drs. C. B. P. Fisher of Bound Brook, Alexander Marcy, Jr., of Riverton, and Luther M. Halsey of Williamstown. The next meeting will take place at Atlantic City in June, 1910.

The Massachusetts Medical Society, at its 128th annual meeting in Boston, on June 16, 1909, elected the following officers: *President*, Dr. Silas D. Presbrey of Taunton; *Vice-President*, Dr. J. C. Pinkham of Lynn; *Secretary*, Dr. Walter L. Burrage of Boston; and *Librarian*, Dr. Edwin H. Brigham of Boston; *Treasurer*, Dr. Edward M. Buckingham of Brookline. Dr. Francis W. Goss, who had served the society as secretary for thirty-four years, refused reelection.

The Lowndes County (Ga.) Medical Society was formed recently. The following officers were elected: *President*, Dr. J. M. Smith; *Vice-President*, Dr. S. T. Harris; *Secretary and Treasurer*, Dr. P. C. Quarterman.

The Maine Medical Association met at Portland, Maine, June 16-18. The following officers were elected: *President*, Galen Woodcock of Bangor; *Vice-Presidents*, Stanley P. Warren of Portland, S. E. Webber of Calais; *Secretary*, W. Bean Moulton of Portland; *Treasurer*, E. W. Gehring of Portland; *Delegate to American Medical Association*, Alfred D. Sawyer of Fort Fairfield.

The International Hahnemannian Association of Homeopathic Physicians at a meeting in Pittsburg elected the following officers: *President*, Dr. S. H. Stanton of New York; *Vice-President*, Dr. E. A. Taylor of Chicago; *Treasurer*, Dr. P. A. Kirchbaum of Montclair, N. J., and *Secretary*, Dr. J. B. S. King of Chicago. The next convention will be held in Kansas City.

The Iowa State Medical Association at its recent meeting selected Des Moines as its next convention place and elected the following officers: *President*, G. E. Crawford of Cedar Rapids; *Vice-Presidents*, Dr. N. M. Bolding of Cherokee and Dr. H. H. Clark of McGregor; *Secretary*, Dr. V. L. Treynor of Council Bluffs; *Treasurer*, Dr. W. B. Small of Waterloo; *Delegate to American Medical Association*, Dr. A. L. Wright of Carroll.

Alumni Society of the New York Skin and Cancer Hospital.—At a recent meeting of this society the following officers were elected for the ensuing year: *President*, Dr. Jerome Kingsbury; *Vice-Presidents*, Drs. J. T. Gwathmey and O. M. Wilson; *Treasurer*, Dr. H. A. Pulsford; *Secretary*, Dr. Fred Wise.

Obituary Notes.—Dr. Joseph O'Grady of Brooklyn died at his home, on June 22, aged 57 years. Dr. O'Grady was a graduate of the Bellevue Hospital Medical School in 1883, and was for many years connected with the Department of Health. He was a member of the Kings County Medical Society.

Dr. Justin Steer of St. Louis died suddenly, on June 20, aged 60 years. Dr. Steer was a graduate of the New York University Medical College in 1876. He was Professor of Clinical Medicine at Washington University and well known as a specialist on diseases of the lungs. He was a member of the St. Louis Medical Society, Missouri State Medical Association, American Medical Association, and the American Association for the Advancement of Science.

Dr. O. E. Phillipi of Fremont, Ohio, died on June 12, aged 73 years. Dr. Phillipi had practised in his town for over fifty years.

Dr. John Quill of Wallingford, Conn., died at his home, on June 17, of tuberculosis, aged 62 years. He attended the Yale Medical School and in 1876 received the degree of M.D. from the New York Homeopathic Medical College. He was for fourteen years physician to the Masonic Home in his town.

Dr. Thomas Paton Wilson, formerly of Cleveland and Detroit, died in Montclair, N. J., on June 23, aged 78 years. Dr. Wilson was one of the best known homeopathic physicians in America. After studying in Berlin and Vienna he was chosen President of the Pulte Homeopathic Medical College in Cincinnati and later accepted the chair of

therapeutics in the University of Michigan. He has not practised since 1886. Dr. Wilson in 1875 wrote a book, "The Horseless City," foretelling the use of horseless vehicles.

Dr. Quitman Kohnke of New Orleans died, on June 26, at his summer home in Covington, La., aged 52 years. He was a graduate of the Medical Department of Tulane University in 1890.

Dr. George Heron of Washington, D. C., died suddenly of apoplexy, aged 72 years. Dr. Heron was a veteran of the Civil War and had practised medicine in Washington for forty years.

Dr. Franklin L. Meyer of Newark, N. J., died at his home on June 26, aged 55 years. He was a graduate of the Bellevue Hospital Medical College in 1887.

Dr. Robert J. Hess died from pneumonia at Philadelphia on June 18 at the age of 63 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1871, and he was for many years resident physician of the Northern Dispensary. He served with the Emergency Corps during the Civil war when he was but 15 years old.

Dr. John Weisgerber died at Philadelphia on June 23 at the age of 43 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1889.

Correspondence.

THE SANATORIUM TREATMENT OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—In Dr. Fishberg's very interesting paper on "The Inadequacy of the Sanatorium Treatment of Tuberculosis" in the Medical Record of June 12 reference is made to the possibility of absurd conclusions in attempting to make deductions from unrelated facts, yet I fear that in an otherwise temperate article the doctor falls into the very error he warns against. Apparently his favorite arguments against the justifiability of sanatoria are: (1) The undisputed fact that existing sanatoria are able to provide beds for but a ridiculously small fraction of the enormous number of tuberculous individuals requiring treatment; (2) that a certain number of patients get well without any sanatorium treatment, and some without any treatment whatsoever. From this he contends that sanatoria for the treatment of tuberculosis are serious blunders from a medical as well as an economic standpoint, and their duplication in sufficient number to meet the situation is to be discouraged as a financial impossibility. It might just as well be argued that, there being a large number of people in the world unaffiliated with any church or religious order who yet remain decent in their morals and business methods, therefore the churches, etc., are monuments to man's stupidity and wastefulness, because the number of those actually obtaining spiritual benefit at their hands is insufficient for the time and treasure expended in maintaining them, which very few will believe; or, because many cases of wayward and criminal conduct remain unreached by the influences of correctional, punitive, and restraining institutions, these, like the sanatoria, are so inadequate in their work as to make their erection and maintenance a grossly mistaken policy by the State; or, again, because in the nature of things a goodly number of cases of physical distress and want must remain unrelieved by existing hospital and eleemosynary organizations, all systems of relief—orphanages, asylums, and the various phases of public and private philanthropy—have demonstrated their incompetency.

What does the doctor propose, for this generation at least, in place of sanatorium treatment, with its shortcomings, for that large class of tuberculous individuals of which he has such intimate knowledge—the indigent sweatshop laborer, mechanic, and artisan, whose homes as such practically cease to exist with the incidence of active disease in the bread winner? What "home" treatment is possible for the head of a family who can no longer perform the office of home keeper—who has become a burden instead of a support for those dependent upon him? This is just the class, Mr. Editor, that the Montefiore Home Country Sanitarium and many kindred institutions seek to reach and relieve, and which they do help—not in the measure that we all wish, it is true, yet the assistance is definite and lasting enough in a sufficient number of cases amply to justify every penny expended for their erection and support. Failures there are enough, but is this not true of every scheme of mankind for the alleviation of human misery? And the inadequacy of the measure is not the fault of the sanatoria, but the callous attitude of a large part of the prosperous public which permits a few devoted men and women to shoulder a burden in which all should have some share.

The doctor is in error in stating that only the incipient cases are accepted by the sanatoria. With but few exceptions, all the sanatoria admit a mixed class, rejecting only those hopelessly ill—and not, as the doctor implies, because these would unfavorably influence statistics, but because of the highly unfavorable psychical effect which dying patients will have on those who come to us hoping for recovery. The number of incipient cases in most places averages little more than 50 per cent. Indeed, it has been found impossible to fill sanatoria with exclusively incipient cases, not because they do not exist in sufficient number, but because it is exceedingly difficult to induce such individuals, who do not feel seriously ill, to give up their means of livelihood for a long period of time.

The doctor criticises the ultimate results attained by the sanatorium treatment, in so far as they are measurable, but he cannot offset the figures, despite their paucity, by anything save guesswork when he considers the ultimate results of treatment outside sanatoria. They are not as good as they should be, therefore another argument against the usefulness of such institutions. Who is there who claims perfection for the routine institutional treatment of tuberculosis? Does not the average man look upon it merely as a beginning, a foundation, for that treatment which is not to cease during the patient's life? And then the relapses, of which the doctor speaks much. Why should these be held forth as arguments against the utility of a given procedure? With the departure of the patient from the sanatorium the latter's rôle as foster mother ceases; other influences become operative, which may be innocuous or the reverse, more commonly the latter. But this is beyond the domain of the sanatorium as it now exists. It is a social and a sociological problem, which humanity will, I am confident, grapple with and ultimately solve. Shall we in the meantime cast aside a weapon which is clearing the ground for the struggle, if it is doing no more? Because of the admitted complexity and difficulties of the situation we should rather strengthen an agency that has made the first forward step in the assault on the citadel of a widespread disease—perhaps only a sortie—with many tactical errors, but at any rate the first definite one which mankind has made in the determination to overthrow a strongly-entrenched enemy.

L. Rosenberg, M.D.

Montefiore Home Country Sanitarium, Bedford Station, N. Y.

THE SENDING OF TUBERCULOUS PATIENTS FROM HOME.

To the Editor of the Medical Record:

Sir:—For a wholly unselfish purpose, I hope you will permit me to trespass upon your world-read columns to state a few facts and to urge upon the profession what I believe to be some practical conclusions.

Persons afflicted with general tuberculosis are being sent into the West and the Southwest by the hundreds every year. Many, probably most, of these persons are beyond all hope of recovery before they leave home. They have heard marvelous stories of recoveries, many of them largely fabricated, generally arising from irresponsible sources, and seem to conclude that a few weeks' more or less pleasant sojourn amid the blue skies of the Southwest will be all sufficient to restore them to robust health. The medical profession must bear a large share of the blame for sending some of the hundreds of pitiably hopeless cases to

this region. Many sufferers arrive here with preconceived opinions that reflect no credit upon their medical advisors. "Just go out to New Mexico and rough it on a ranch." This to a patient with an afternoon temperature of three degrees above the normal! It is useless to multiply individual instances illustrating the folly met with here every day. Miracles are not wrought in the Southwest or elsewhere. That a large region of our Southwestern country presents a favorable climate for the cure of some cases of incipient tuberculosis is nowhere denied; but climate is, as every experienced physician knows, only a small element, after all, in the treatment of tuberculosis. A favorable climate does help in properly selected cases, but I believe that this is as far as any scientific observer ought to go in talking with a patient. Some persons afflicted with tuberculosis in its milder forms undoubtedly recover in New Mexico, as they do in New York, Massachusetts, Ohio, and Illinois. My private judgment is that a good doctor, with some practical wisdom at command, is of vastly more importance than any climate on the face of the earth.

Another idea that seems to have taken deep root in the minds of some superficial observers might be expressed in these words: "the greater the discomfort the more certain the cure." Just get into a rickety tent, with a howling wind, plenty of dust, and all the elements of human misery at every turn, dress in the cold, lie awake and listen to the fitful gusts of wind and the cheerful notes of the prairie owl, and a sure cure is in sight. The tent nuisance has probably seen its best days. Just what there is, or ever was, about a tent to attract oxygen I have never been able to conceive.

What I now say is meant in no spirit of harshness, but it does appear that most of the patients who arrive in this region from the East seem to have left all of the saving grace of common sense behind them. They arrive without woolen underwear or overcoats, forgetting that nearly every night in this region is cool enough to require a woolen blanket and that even a short night ride over the plains demands warm covering. My heavy winter gloves are this moment loaned to a well-meaning tenderfoot from New York, who imagined he was landing in a lime-kiln when he got off his train. In conclusion, there is an economic feature that must have a plain word. Men and women must be fed, clothed, and sheltered in New York, even when well: why should sick people expect to recover from a malignant disease in New Mexico on pure air alone? Sick people seldom perform any profitable work in New York or Chicago, and why should they expect to work wonders in New Mexico? My final advice is, to any person afflicted with tuberculosis, if you want to get well, instead of spending fifty dollars for a ticket to New Mexico, invest a hundred dollars in your home doctor, being sure that you get a hundred dollar man, and accept his advice.

HOWARD CRUTCHER, M.D.

ROSWELL, NEW MEXICO, June 8, 1909.

RESPONSIBILITY FOR THE MEDICAL FEE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—We doctors are notoriously poor business men. We do not collect much more than half of what we earn because we are not up to date in our methods of transacting our business. We take up a patient, give him the best we have to offer of our time and effort and after it is all over we have to fight to get our fee. And sometimes the law is against us because of our ignorance of its technicalities.

Here is an illustration from a recent experience: Some time ago I was summoned by a 'phone message to a nearby factory to attend an employee who had her finger crushed while working at her sewing machine. I explained that I was not a general practitioner and suggested that a neighbor of mine be sent for. To this the man at the 'phone demurred, saying that the girl was in great pain and bleeding very much and urging me to come over. To this I consented. I treated the girl's finger and at the request of the girl and the man in the office I agreed to treat her until she was cured. After dressing the finger I went to the office and asked to be paid. The man in charge said: "Doctor, the girl will need further treatment. You treat her until she is cured and then send us the bill. We are insured against accidents. What will the fees be?" I told him and to this he agreed. The girl came to my office sixteen times and the damage was repaired with very good result. The bill was sent to the firm. No response. I then called in person, and was told by the head of the firm that he would pay the bill if it were cut in half. This I refused on the grounds that the fee had been agreed to in advance, and that it was a moderate one for the services rendered. After some words, in which the proprietor showed himself a master of profanity, I threatened to sue if the bill were not paid in twenty-four hours. Suit was brought. At the trial my lawyer brought out the facts in the case—how the man in charge of the office summoned me, that a fixed fee per visit was agreed to by him for the firm, that the services were rendered; also that the head of the firm offered to pay what he thought was the proper fee, and so forth. On cross examination I was asked if the head of the firm or his partner was present when I was engaged to treat the girl, to which I responded in the negative. The head of the firm went on the stand and in response to his lawyer's questions stated under oath that neither he nor his partner had engaged me to treat the girl, and that nobody in their employ had any authority to engage any doctor in case of accident to any of their employees. In other words, that the man who engaged me had no authority to do so at the expense of his firm. And I lost my case.

Here is the point I wish to make. When we are called to treat a person it is our duty first to find out by whose authority the call is made and whether those who are to pay have given this person the right to act for them.

M. D

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PUBLIC HEALTH AND POOR LAW STATISTICS—A PENTOSE IN URINE IN PANCREATIC CASES—CANCER, AGE INCIDENCE IN MAN AND ANIMALS—ASTHENOPIA—DR. LUCAS-CHAMPIONIÈRE AT CARDIFF—LIVERPOOL HOSPITAL SCHOOL—OBITUARY.

LONDON, June 11, 1909.

THE Local Government Board has issued a volume of statistics concerning the two great departments of administration which it controls, Public Health and the Poor Law. Moreover, it has presented its figures flanked with statistics from other departments which assist in their comprehension. The book is copiously illustrated by maps and charts and gives a view of the changes in the life of the nation as complete as existing data allow. There are six sections illustrating as many divisions, but I can only refer to points relating more or less directly to medical or sanitary matters. During fifty years the population of England and Wales has practically doubled. A falling birth rate is more than neutralized by a falling death rate, which has been reduced from 22 to 15 per 1,000. Pauperism has decreased and thrift has increased; but the attraction of the towns for country people is persistent. In 1851 the men employed in agriculture were one in four: now they are only one in ten. For every 100 persons then living in London there are now 203, and in the 84 next largest towns the increase in the half century is greater, viz., 282 as against 100 in 1851. Nevertheless, the figures and charts demonstrate the success of the medical and sanitary campaign against numerous forms of disease. They show, too, that the death rate is falling even in these town areas. Typhus, typhoid, variola, scarlatina, diphtheria, tuberculosis all give proofs of the success. On the contrary, infantile mortality is still excessive. In 1907 it was 188 per 1,000. But even this rate is exceeded by all other countries except Holland, from which statistics are available. The local sanitary authorities are not as a rule insensible to the urgency of this state of infantile mortality and about 150 have appointed health visitors to give personal instruction in hygiene and motherhood. Of course, the expenditure of these authorities has enormously increased. The medical and sanitary services in 1870 were costing in urban districts something under £5,000,000 annually. To-day the expenditure is more than £20,000,000, and this will certainly go on increasing, for there is much land to be taken up. It is not without economical result, for the expectation of life in towns is now greater than it was in rural areas thirty years ago.

Dr. P. J. Cammidge reported to the Royal Society, on the 20th ult., that he had isolated from the urine of patients with disease of the pancreas a sugar which gives the reactions of a pentose and yields an osazone with a melting point of 178° to 180° C. He had not at present isolated the mother substance, but thought it was probably set free as the result of degenerative

changes in the pancreas and passing into the blood was removed by the kidney. The substance could not be obtained from normal urine, nor from that of patients having no signs of pancreatic affection. In 28 cases of such affection the observation had been confirmed at the post mortem. Moreover, in three days traumatic pancreatitis had been produced and the same body obtained from their urine.

At the Royal Society also Drs. Bashford and J. A. Murray related some further observations confirming their statements in 1904 as to the age incidence of cancer in animals. They also gave statistical confirmation of their previous results for the Imperial Cancer Research Fund, showing the close parallel, in many points complete identity between malignant growths in man and other vertebrates. The law of age incidence of cancer holds for the shortest-lived mammals just as for man. The facts as to other vertebrates, so far as they are known, point to the same conclusion. The law of age incidence is therefore most likely a general one, of course proportionate to the relative expectation of life in different animals. Any explanation of the etiology of cancer must therefore assent, these authors accord, with the circumstance that "when considered statistically cancer is a function of age, when considered biologically a function of senescence."

The Edinburgh Medico-Chirurgical Society has had a discussion on asthenopia. Mr. George Berry, who opened, preferred the older term to eyestrain, as when qualified by appropriate adjectives it would convey a definite meaning. Cases in which watering of the eyes and conjunctival or corneal irritation were prominent were often produced by working or reading in unsuitable light, particularly if the actinic rays were abundant. Reading in bed was more likely to strain by the light being insufficient, *e.g.* a single candle. With errors of refraction Mr. Berry held that lid-pressure was the cause of headache. A patient with slight astigmatism could temporarily improve vision by compressing the globe, as by frowning—a fact demonstrable by the ophthalmometer. He did not use cyclopegics, as their effect on astigmatism was only due to the dilatation of the pupil. He attached no importance to some degree of divergence or convergence. But marked deviation of one eye upward or downward was due to anatomical asymmetry of the orbit and could be corrected by prisms. Many cases were due to nervous or hysterical states, and he had cured some by subcutaneous injections of distilled water. Some cases of migraine were due to errors of refraction and some he thought might be traced to gout.

Dr. George Mackay said that though lid-pressure caused discomfort to astigmatics he thought that the action of the ciliary muscle also contributed. Cyclopegics were occasionally useful for studying more thoroughly refractive error in difficult cases.

Dr. Lyne agreed that slight divergence or convergence had been overruled and discussed the defects producing migraine.

Dr. Sinclair found many cases of hypermetropia were temporary and a patient whose health had run down could be helped by glasses and put them aside when he recovered.

Dr. Main, from experience in China, stated that the intense glare of the western sun caused no discomfort to the Chinese, even on prolonged exposure to it.

Dr. Lundie discussed the greater discomfort caused by the lesser degrees of error.

Dr. Thyne said refractive error did not cause a special form of headache, so that in any case which could not be traced to another cause the eyes should be carefully examined.

The visit of Dr. Lucas-Championière to Cardiff has evoked the enthusiasm, not only of the Welsh, but of the British profession generally. As the president of the International Surgical Society, he would, of course, have been received with all honor, but his visit was also timed so as to enable him to make the presentation to Mr. Lynn Thomas and Dr. Skyrme, which has been subscribed for by more than 2,000 practitioners. In presenting it he said he was proud to do so, for the occasion was international as well as British. Besides performing this ceremony, which closes the story of perhaps the most manful defense of professional right that has triumphed over all legal obstacles, Dr. Lucas-Championière delivered an address to the Medical Society of Cardiff on the "Modern Treatment of Fractures," the subject which may be termed his own and out of which the troubles ending in the presentation arose. He opened his address by telling how he visited this island early enough to see Listerism at its dawn and that ever since he rendered homage to the science of this country—not because, as some have said, that science has no country, but love of science is an additional sentiment to love of country, embracing all who in foreign countries have enriched science. He then passed on to expound the treatment of which he is the father as appropriate to the occasion because he found the profession here under the influence of the righteous emotion of the whole surgical world due to the unjust accusation made against the two surgeons whose work had been vindicated.

Sir Alfred Jones, speaking the other day of Northern Nigeria, said the work of the Tropical School of Medicine at Liverpool had reduced the death rate in tropical colonies from 25 to 5 per cent., and they had the satisfaction of seeing their work copied by all nations. The Liverpool school had spent £100,000 on this work and had stimulated an expenditure all over the world amounting to two millions devoted to saving life in the tropics.

The death has occurred of Major P. G. Ievers, R.A.M.C., at the age of 56. He had for some time been in charge of Forts Stamford, Staddon, etc. When the South African war broke out he had already retired from the army, but he offered his services and went through the campaign. He qualified in 1873-1874 in Dublin and Edinburgh. In 1881 he contributed "Ten Cases of Enteric Fever Treated by the Cold Bath" to the *Indian Medical Gazette*.

The death was announced yesterday of Henry John Hunt, J.P., late surgeon to the Bath Hospital at Harrogate, where he practised many years. He had also been surgeon to H. M. prison at Petworth.

Dr. Ch. Marshall Kempe, late Medical Officer of Health of Shoreham, died there on the 23d ult., aged 70. He was Medical Officer of Health to the port sanitary authorities and held other offices. He also took a part in municipal work and was greatly esteemed throughout the district where he spent so many years.

Dr. Henry Kay Ramsden died on the 1st inst. of malignant disease of the lung, aged 42. He was the son of a medical man and one of four sons, all of whom joined the protession. He served as a civil surgeon in the South African war.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

ANESTHESIA—PERITONITIS—ABDOMINAL COMPRESSION—BRAIN PUNCTURE—TRANSPLANTATIONS—CLEFT PALATE—ABSCESSES—MESSINA—ROENTGEN SOCIETY.

BERLIN, May 15, 1909.

THE early spring is in Berlin the height of the season of congresses. The Congress of the German Surgical Society, the Roentgen Congress, the Congress of the German Society of Tropical Medicine, the Congress of the German Urological Society, the Congress of the Orthopedic Society, and several others of minor importance have been held. It is at present impossible to give even a superficial review of the vast material covered by these congresses and I will, therefore, pick out but a few special subjects.

The Surgical Congress discussed extensively the subject of anesthesia. Among 71,000 inhalation anesthesias collected by members there were reported some 3,000 fatalities. The combination of scopalamine and morphine with the ether seemed to be best. The universal verdict favored tropococaine for spinal anesthesia in preference to all other drugs, Bier combining it with adrenal extract, von Ehrhardt with arabinic acid. A series of illustrated lectures demonstrated the great value of *x*-rays in surgical diseases of the abdomen. It appeared that the method of treating purulent peritonitis by vigorous washing of the abdominal cavity with large quantities of salt solution was winning more and more followers. Momburg, basing his remarks on an extensive material, brought up the discussion of a new therapeutic method. He obtained anemia of the abdomen by applying an Esmarch's rubber bandage firmly to the waist and so produced anemia of the entire lower portion of the body. The method was of great value both to surgeons and to obstetricians in controlling atonic postpartum hemorrhage. It was striking to see the powerful uterine contraction which occurred with the renewal of the circulation following the constriction. No bad results of the procedure had been observed as yet.

The old belief that the abdominal organs were with-

out sensation of pain did not seem to be confirmed by experimental research, and general anesthetics should be used in abdominal operation. Bramann of Halle had the opportunity of puncturing the corpus collosum in twenty-two cases in brain surgery. The purpose of the procedure was that in cases of increased intracerebral pressure a communication between the ventricles and the subdural space was made by perforation of the corpus collosum. Krause recommended in removing cerebral tumors the use of a suction pump to suck out the tumor mass.

The subject of transplantations also came up for prolonged consideration, as Unger was able to report a series of experiments carried out by Carrel of New York, in which he succeeded in implanting foreign kidneys into an animal. One dog lived for eighteen days with kidneys secreting normally. It was said that in bone transplantation the best results were obtained when the bone was transplanted with the periosteum. In animal experiments entire joints had been transplanted and had healed. In severe cases of complicated fractures of the extremities the "nail extension" method of Steinmann of Berne seemed to be winning more and more adherents. Helbing had been able to close extensive cleft palates by a new procedure. By the use of a metal bow he succeeded in approximating the two halves of the maxilla one to two centimeters in four to five weeks. Cold abscesses, according to Kollaczeck of Tübingen, could be treated by puncture if an antiferment were injected into the abscess cavity. The method was said to be ideal in cases with intact skin and smooth abscess walls. Colmers of Heidelberg, the chief of the German Relief Expedition to the Messina earthquake, has collected his experiences. He reported that as at the time of the shock most of the people were asleep the injuries were severe. As many were wedged for a long time between the ruins, in most cases decubitus and phlegmon were added to the severe lacerations. Often pressure paralyses were seen. In smaller injuries the scalp often suffered and bald spots—alopecia traumatica—were formed.

At the Congress of the Roentgen Society Albers-Schönberg brought up the treatment of myomata by the *x*-ray. Cessatio mensum could also be obtained by this method. The good results were confirmed by many speakers. The question of dosage in *x*-rays was much discussed. A uniform method of measuring the rays had not been obtained. Various animal experiments showed that great care was still required in using the *x*-rays. A goat was shown which a year previously had been exposed for thirty minutes to the rays. This half of the animal had ceased in its growth. Seven theses on *x*-ray injuries were presented by Gocht of Halle and a commission appointed to adjudge them. The further development of research in technique points toward using the shortest possible exposure. Grodel of Nauheim demonstrated various *x*-ray kinematograph pictures of the heart.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 17, 1909.

Diagnosis and Prognosis of Gallstone Disease from the Point of View of the Surgeon.—This question is considered carefully by M. H. Richardson, who asks why the diagnosis is in the majority of cases difficult. It is the wide variability of lesions and the still wider variations in their effects upon the patient and the latter's power of expressing his feelings in words. Besides gallstones, the following may cause pain in the right upper quadrant: (1) infection of the gall-bladder or ducts without stones (though the latter may have been expelled), (2) organic and functional diseases of the stomach and duodenum, (3) certain diseases of the right kidney, (4) appendicitis when the appendix is high, and (5) certain other rare conditions. The weight of evidence in favor of gallstones must come from a history of pain, and the recognition of it and of its significance is, in the great majority of cases, the diagnosis. A multitude of operations have proved the following facts: that with certain subjective symptoms gallstones are found, that the pathological condition found is sufficient to account for the symptoms present, that after removal of the stones causing distinct pathological changes the symptoms cease, that symptoms cease after the removal of gallstones which have caused no perceptible anatomical change, that the symptoms do not always cease after removal of gallstones, whether organic lesions are found or not, and that symptoms often cease after the draining of the gallbladder when no gallstones have been found. There are, broadly speaking, four classes of gall bladder cases (1) the stone offending slightly or not at all, (2) the successfully expelled stones (3) the impacted stones, and (4) the infected tract. "Shall we wait," asks the author, "for pathological changes of serious diseases to become so characteristic that diagnosis is unmistakable?" He replies: "We must study disease as we study the enemy in war. We must make our attack at the earliest possible moment after we have with reasonable accuracy located the enemy and ascertained his resources. Until the surgeon has taken all reasonable and safe precautions to make as positive diagnosis as can be made, he has no right to operate for gallstones or any other lesion. When he thus fails to make the diagnosis an error means increased suffering and ill health or death and disability; he must resort to an exploratory incision, and he can then with a clear conscience so do.

New York Medical Journal, June 19, 1909.

Some Indications for the Removal of the Faucial Tonsil and Suggestions as to Its Technique.—G. Hudson-Makuen discusses the modern aspects of the tonsil question and makes the following observations. The normal faucial tonsil is small and scarcely demonstrable without the aid of a palate retractor. The function of the faucial tonsil is still in doubt, although it is probably to guard against bacterial invasion of the system. The protective influence of the faucial tonsil, however, is destroyed as soon as the gland becomes diseased. The usual symptoms arising from the diseased faucial tonsils are sore throat, irritating cough, and foul smelling breath. The diseased faucial tonsil is a distinct menace, both to the organs of special sense in its immediate neighborhood and to the general health of the individual. The large faucial tonsil is not only unhygienic, but it is also obstructive to respiration, phonation, and articulation. The faucial tonsil may be very large or very small and its size is no criterion as to the extent of its disease. The rather common belief among the laity that the removal of the faucial tonsils impairs the voice is altogether without foundation, except in those cases in which injury is done to the palate or other surrounding structures. The largest faucial tonsil often appears small because it is held within the grasp of the faucial pillars and buried in the tissues of the neck. The so-called submerged faucial tonsils are especially harmful and difficult to remove. The chronically diseased faucial tonsil should be removed in its entirety, because remnants do not easily drain their crypts into the pharynx, and the secretions are more readily absorbed into the system. The base of a submerged tonsil left in a deep tonsillar fossa afterward protrudes itself into the fauces and leads to the supposition that the tonsil is returning. The tonsil is best removed under local anesthesia when the complete cooperation of the patient may be secured. General anesthesia is more satisfactory and safer in children, and should always be used when an adenoid is also to be removed. The faucial tonsils should be removed first, care being taken that all hemorrhage is controlled before going from one tonsil to the other. The instruments used in the operation vary with each individual case, and celerity in the performance of the operation should be sacrificed to thoroughness.

Some Practical Lessons from a Study of Two Hundred Cases of Weakened Feet.—J. M. Berry calls attention to the fact that pain in the back and limbs, pain and weakness in the knees, weak ankles, inability to skate, etc., may indicate that the primary trouble is in a weakened foot and ankle. Improper shoes are the main causative factor. Some trauma may call attention to a trouble which has existed for some time. A painful and enlarged big toe joint is very common in weakened conditions of the feet. Whenever callus forms on a foot something is wrong. One of the most difficult conditions to differentiate from weakened feet is intermittent claudication or limping. In some cases of this disease practically all the symptoms are referable to the feet; in fact, the disease may produce a weakened condition of the feet and the patient suffers from both conditions at the same time. The characteristic symptom that distinguishes intermittent claudication from weakened feet is that in intermittent claudication, while the pain and discomfort in the feet from walking may become almost unbearable, after a short rest the trouble clears up and the patient can go on again. A diagnosis of intermittent claudication

is of special value as regards prognosis. Shoes and braces and other appropriate treatment for weakened feet will aid the patient in so far as the weakened condition of the feet is concerned, but will not, of course, cure the intermittent claudication. An important aid to treatment of weakened feet is to get the patient interested in what is being done. Get him to further the process of cure by home gymnastics, massage, etc. The home treatment of weak feet would make a good subject matter for an article. Another important element in the treatment is the careful supervision of the patient. The patients have to be told that the braces are going to be uncomfortable at first. It is not a good plan to let them wear the braces home from the office, but wait and put them on at home in the morning, wear them as long as possible, then remove them, and when the feet are rested put the braces back again, remembering that the more they wear them the quicker they will get used to them. The patient should report every few days for massage and vibratory treatment. This helps a great deal in overcoming the stiffness of the foot and in relieving the pain and discomfort of braces.

An Expeditious Method for Submucous Resection of the Triangular Cartilage of the Nose.—W. P. Porcher's patient was a man of fifty-nine, whose triangular cartilage was dislocated on the right side, causing considerable flattening of the end of the nose, and almost complete occlusion of that nostril. The pateney of the tubes on both sides was very poor. In consequence of his deafness his enunciation had also become seriously affected, so that he could neither speak distinctly nor hear when spoken to, and his breathing while asleep was very stertorous. After dissecting up the mucous membrane over the dislocated portion of cartilage, the author determined to use the electric trephine instead of the knife or forceps because the cartilage proved to be very tough and situated somewhat further back in the nose than usual. With a rather long Curtis trephine two large cones of cartilage were drilled away, the trephine passing through the mucous membrane in the rear. When we remember how rapidly the trephine works we can appreciate the quickness, simplicity, and ease with which the operation was performed. The projecting ends of the cartilage having been removed, the septum resumed its erect position. The mucous membrane was allowed to fall back into position, and a compress of cotton was used to hold it so until union took place, which was by first intention.

Journal of the American Medical Association, June 19, 1909.

Phagocytosis.—F. M. Pottenger offers the following conclusions, deduced from experiments with the blood of various patients presenting considerable variation in the number of cells belonging to the different classes of Arneth, in order to determine if the different classes of cells retained a constant relative phagocytic power: "1. There is more or less definite phagocytic value for each variety of neutrophile (Arneth's classification) acting on staphylococci. 2. This fact will surely throw light on the varying phagocytic values of neutrophiles obtained from various sources. 3. It may aid in the solution of the question of leucocytosis induced for therapeutic purposes. 4. It is evident that Wright's early assumption, namely, that the leucocyte is a comparatively indifferent factor, is wrong."

Scissors-Magnet Extraction of Foreign Bodies from the Eyeball.—E. Jackson points out that in a considerable number of cases the electromagnet, whatever its form and however used, fails to remove pieces of iron capable of magnetic attraction from the eyeball on account of their being embedded too firmly in recent exudate or organized tissue. In such cases he thinks we have a resource in the use of scissors attached to the magnet, and he reports two cases in which this method was successfully used. Somewhat similar methods with a knife or strabismus hook attached to the magnet have been reported by Connor and Lang, but this is different from the use of the magnet force to direct a cutting instrument to the foreign body as used by him. The special technique of introducing the scissors and a description of the instrument is also given. The article is illustrated.

The Faucial Tonsils and the Teeth.—G. Hudson-Makuen emphasizes the importance of the faucial tonsils from the dentist's standpoint. Diseased faucial tonsils affect the teeth in three ways: First, by impairing the general nutrition; second, by contributing very largely to the local invasion of the teeth by the numerous bacteria that infest their crypts; and third, by their pressure, they interfere with the alignment of the teeth and with the normal development of the maxillary bones. That diseased tonsils affect the general health has been proved beyond the shadow of a doubt and the teeth suffer with it, as well as directly by contact with its filthy catarrhal secretion. The third manner in which the teeth are affected by hypertrophied tonsils has, so far as Makuen is aware, not been mentioned in the literature, but he considers it of no little importance. These glands are sometimes very large and dense, and their constant pressure on the surrounding structures may cause changes that will seriously embarrass the normal circulation and respiration, produce neuralgias, etc., as well as interfering with the normal development and arrangement of the teeth. The indirect effect of diseased and hypertrophied tonsils on the teeth and their settings through forced mouth-breathing, has been described fully by numerous observers. Makuen pleads, therefore, for the eradication of all glandular obstructions to the normal development of the teeth and alveolar arches, prior to any attempt to remedy the structural defects of these organs. He thus sums up his conclusions. The faucial tonsils and the teeth are in close approximation and they are alike subject to disease or degeneration. Diseased tonsils and teeth are locally and systematically unhygienic. Secretions from the tonsils may infect the teeth, and, contrariwise, the tonsils may be infected by the teeth. Diseased tonsils and teeth cause headache, earache, and facial neuralgia, and they become a direct source of infection to the glands of the neck and, through the efferent lymphatics, to the general respiratory and circulatory systems. Hypertrophied faucial tonsils often become so large as to affect the ear, the circulation of blood, the nerve supply of the face and head, and the normal development of the alveolar arches. The teeth serve important purposes, but the exact function of the tonsil has not yet been demonstrated. The importance of preserving the teeth has been fully recognized, but the diseased tonsil is not worth preserving, for it has lost its usefulness and becomes a menace to the human economy. The only rational remedy for diseased tonsils is total extirpation.

Amebic Dysentery.—Granville S. Hanes remarks that it was recently believed that amebic dysentery was purely a tropical disease or acquired only in those regions. A theory has been suggested, that cases occurring in our climate are due to eating uncooked tropical fruits on which the ameba had been imported. There is no scientific evidence in the support of this theory and cases occur in which its possibility can be excluded. He and his partner Dr. Mathews have had half a dozen such cases under their care in the past few months, two of which are reported. In both of these the evidence was strongly in favor of impure drinking water as the cause. He thinks that amebæ are indigenous in this country, but the less favorable environment than in the tropics renders them less in number and virulence, and the disease caused by them is consequently rarer and less severe. The diagnosis is always made with the microscope and he does not rely on the examinations of the dejections alone, but inverts the patient and scrapes the ulcers with a sharp curette. In this way the amebæ will be observed at once if they can be found at all. It may be difficult to find motile amebæ, while the patient is under actual treatment, and in such cases he discontinues the treatment for a few days and they appear again. Warming the stage is also an important measure in detecting them under the microscope. He is convinced that there are large numbers of people in this country suffering from unrecognized amebic dpsentery, cancer or tuberculosis being the most usual diagnosis after the patient becomes emaciated. No one plan of treatment has been found universally successful and relapses are always to be anticipated as possible. When the interval, however, is a number of years, Hanes thinks we should consider reinfection as the possible cause. There is nothing that will prevent possible reinfection as long as the patient's environment is unchanged. Too restricted diet he thinks is a great mistake in these cases, but rest is an important feature in the treatment of the disease. Of remedies given internally, ipecacuanha is the most to be relied on. It does not perhaps kill the ameba but it destroys its pathogenic power. A large number of parasiticide injections have been employed but none is universally effective. Quinine has been largely used but it is sometimes an absolute failure. Hanes has employed coal oil, knowing its generally parasiticide effects. He at first employed it with great caution, but latterly has come to use it with boldness, and he now has no hesitancy in injecting a quart or more of undiluted coal oil through the rectum or, in the cases of appendicostomy, through the appendix, the patient being then requested to

keep the recumbent posture for half an hour or longer. He is not prepared to make definite statements as to the influence of oil on the amebæ, but expects to be able to do so in the future. All the patients in whom he has employed this treatment except two have responded beautifully. In the two cases mentioned he was not allowed to carry out the method in detail, and he has advised appendicostomy and will keep the patients under observation and report later on the results.

The Lancet, June 12, 1909.

Preliminary Note on the Vaccine Treatment of Typhoid Fever.—A tabulated statement is presented by D. Semple. His conclusions follow: (1) It will be seen that the administration of bacterial vaccines in cases of enteric fever is a practical method of increasing the bacteriotropic substances in the blood as evidenced by an increase in the opsonic index of those treated by this method. (2) When appropriate doses are given the method is devoid of all risks, is easily carried out, produces no apparent disturbance in the patient's condition and does not interfere with any other treatment the physician may deem necessary. (3) It would not be possible to generalize from the few cases here recorded as to whether vaccine has a marked effect in cutting short the fever period. Two cases treated with stock vaccine and two with autogenous vaccines would seem to indicate that it may have this effect. (4) In six of the nine cases here recorded, well-marked improvement set in after the inoculations. This was especially noticeable in the two cases treated with the autogenous vaccines. In the remaining three there was an amelioration of the clinical symptoms.

Surgical Treatment of Colitis.—The paper of G. Heaton considers the question from the modern surgical standpoint but presents nothing new. Excluding specific infections like dysentery and various secondary affections, he divides the colonic inflammations into (1) acute and simple chronic colitis, (2) mucomembranous colitis, (3) acute ulcerative colitis and (4) chronic ulcerative colitis. Simple acute colitis is purely a medical disease. In simple chronic colitis we have a malady liable to extend at any time to the appendix. When this becomes periodically attacked it should be removed but it should be made clear to the patient that the operation is being undertaken to remove the risk of the bursting of the appendix and that the symptoms which are due to the colitis may still remain. Again, the author says that in some of these cases appendix removal will cure the trouble although the appendix may appear not diseased. For mucomembranous colitis cecostomy and appendicostomy are the operations of choice. The latter is preferable because it is much easier (the shock and risks of operating being practically nil), it is free from the danger of leakage of irritating intestinal contents through the artificial opening which is the great disadvantage of cecostomy, the opening in the appendix can be kept open almost indefinitely and does not confine the patient to the house or render him an invalid, and finally the opening is extremely easy to close. It will close spontaneously very often if not kept open by the regular passage of a catheter. In acute ulcerative colitis, a disease about which we know but little, cecostomy may be performed. In chronic ulcerative colitis, mild measures may be given a prolonged trial but when the diarrhea continues with the passage of blood and mucus and the patient is progressively losing weight and passing into a neurasthenic condition, an appendicostomy with a daily irrigation of the colon will in many cases effect a cure.

Fatal Hemorrhage in the Pons Varolii in a Young Infant.—Sidney Phillips reports the case of a baby breast-fed until the eleventh month and then placed on diluted cow's milk. At the fourteenth month she had a sudden attack of what was thought by the mother to be bronchitis and was taken to hospital. She recovered in a few days and was taken home. One day the mother went out and on her return home found the baby in the position she had left it, unconscious and surrounded by vomitus. She at once took the child back to hospital where it was received comatose and with complete flaccidity of all the limbs. Pupils did not react, knee-jerks were present but not Kernig's sign. No sign of organic disease could be found in chest or abdomen. There were respiratory crises, the respiratory rate rising rapidly and the bronchial tubes being flooded by a copious secretion of mucus with loud rhonchi all over the chest, whereupon the breathing would then become quiet and tranquil, about 14 to 16 per minute. Death came in 14 days after the second admission to hospital. At autopsy, as the brain was removed, some partly altered blood was seen in the subdural space at the base of the brain and extending upward toward the vertex. There was also a collection of recently extravasated blood in the subdural space around the right lateral lobe of the cerebellum. On section of the pons in its right half throughout its whole length was a brownish semi-fluid, apparently a hemorrhage with partial absorption and decomposition of the clot. It came close to the median line but did not reach the surface of the brain at any point and was not in communication with the subdural effusion. The dura was everywhere adherent to the cranial bones, which were roughened. There was no sign of an injury to the skull. The author thinks that the sudden prolonged coma evidently resulted from the hemorrhage into the pons; the subdural hemorrhage was more recent and perhaps gave rise to the slight movements of the lips and arm noticed during the course of the disease. The cause of the bleeding was not explainable. There were no indications of syphilis or cachexia of any sort.

British Medical Journal, June 12, 1909.

Hypertrophic Osteoarthropathy of Hands Without Visceral or Constitutional Disease.—R. C. Worsley reports the case of a man of 47 years and shows four photographs of the manual deformities referred to in the title of his paper. The only other abnormality in the entire family was the fusing of two toes on one foot of a brother. At birth the patient's hands were apparently normal except that the middle finger of the right hand was crooked at the top joint. At two years of age, this and the index finger of that hand and the same two of the left hand began to grow out of proportion to the general rate of growth and the enlargement was most marked from the eighth to the fourteenth year. The only movement now possible is at the metacarpal-phalangeal joint of the deformed fingers, the other fingers and thumbs having normal movements. All the other interphalangeal joints are ankylosed. At most of these joints there are large craggy nodosities which feel cartilaginous and over the dorsal surface of the metacarpophalangeal joints of the first and second fingers of the left hand and middle one of the right are to be felt movable bodies, evidently cartilaginous, of ½ in. to ¾ in. diameter, and one or two smaller pieces like "melon seed bodies." The enlarged fingers are transparent looking at the more distal portions, and traversed by fine pink-colored venules. The palms, especially the left, have huge pachydermatous pads, well seen in the photograph; the smaller pad next the thumb can be picked up, and has a thick, broad pedicle. The man generally carries his hands in his pockets. He is a boot finisher by trade, and says he can make a good living by it when work is plentiful. He has refused any operative interference.

Biotripsis or Life-Wear; Trophic Changes in Old Age.—G. L. Cheatle says that if it can be shown that biotriptic changes (which occur most markedly at areas where there is a special liability to papilloma and cancer) are related to neurotrophic changes, the demonstration would support two theories: 1st that a neurotrophic disturbance is concerned either directly or indirectly with the genesis of cancer, and 2nd, that a neurotrophic influence bears on the direction and limitation of the spread of cancer. The biotriptic changes are observed most commonly on the backs of the hands, the temples and the foreheads of old people, occasionally on the lower lips, cheeks, forearms, and elsewhere. The skin becomes shiny, smooth, thin, inelastic, pigmented, and apparently scarred. The best place for observation is the second metacarpal bone. The condition resembles the bronzing of skin which has been subjected to prolonged exposure to *x*-rays. If we examine people in a country village who have grown up together and have lived the same kind of life, there will be found a great variation in the extent to which these changes have gone. Anesthetic leprosy, Addison's disease, melanodermia, leucodermia, moles, and the grayness seen in the hair of people who are as we say "turning gray" all indicated by their distribution or associated nerve lesions a possible connection between pigmentation and nervous influences. It is surprising that cutaneous pigmentation does not occur with greater frequency after operative and traumatic injuries. Whether pigmentation can be associated in any way with the cancer question or not, is still an open question. It is well known that pigmented cancer represents malignancy of a virulent type. Does the presence of the pigment in the malignant epithelial cells mean that they possess greater resistance and vitality? Experiments show that normal pigmented epithelial cells of variegated guinea pigs possess greater vitality or resisting power than their white epithelial cells when both kinds are grafted on to the same raw surfaces. There is at present no evidence to show that cancer is more frequent in negro than in white races nor can one say that the skin

of brunettes is more liable to cancer than is that of blonds, nor is cancer known to be more common on the pigmented parts of any person, black or white.

Notes on a Thirty Days' Fast.—The record of F. Penny is one of personal experience. He is a physician of 46 years, 5 ft. 7 in. high and previous to 1905 had averaged 157 pounds in weight. Since that date he has been on a purin-free diet and has lost from 10 to 14 pounds. He felt himself to be in good condition but undertook to fast in order to satisfy himself whether the accumulation of waste and unnecessary material in the system is the real cause of much disease or whether a prolonged fast is a sound method of elimination and as such, conducive to better health. He notes in tabular form his vital records on the days of his fast. His drink consisted of distilled water with a little salt added. Bowels acted only after enemata. He thus describes his mode of life during the fasting period: "My time was occupied chiefly in reading, exercise, and conversation. I retired generally between 10 and 11 P.M., and generally spent twelve to fourteen hours in bed with the windows wide open. My average loss of weight was 1 lb. a day. My exercise was walking three miles and a half and cycling five miles and one-fifth a day. After the first two days I felt no hunger. I suffered much from cold, especially in the feet and hands, probably to some extent due to my being too lightly clothed for this climate. At times I was very irritable. Throughout the fast my tongue was coated and my breath offensive. During the last eight days I had very little inclination for exertion of any kind. This fast was broken on the completion of thirty days with 1 lb. of fruit, in spite of eating which my weight dropped 1 lb. during the next seventeen hours, and my urine was loaded with "urates." Then I took fuller meals of milk, rice, fruit, toast, honey, etc., and gained weight rapidly (4½ lb. in two days). I then had some traveling to get through, and on the third day took a long railway journey, including crossing London: on the fourth day I cycled fifteen miles, and took another long railway journey, and during the following night I had acute dyspepsia with very violent diarrhea, which latter continued, with intermissions, for three days. After this I ate well and steadily, gained weight (10 lb. in ten days). During the third week my mouth was very tender, and my sublingual glands were considerably swollen, and during this week I gained 3 lb. in weight. For some days during the second and third weeks there was very free diuresis. This fast was not carried to a finish—that is, until my tongue cleaned and natural hunger returned, as described by Dr. Dewey—and I have not yet completely satisfied myself with regard to the objects for which the fast was undertaken, but I hope for better success next time."

Deutsche medizinische Wochenschrift, May 20, 1909.

The Relation of the Pancreas to Achylia and Anacidity of the Stomach.—Ehrmann and Lederer discuss the earlier literature on the relation to acidity in the stomach to the secretion of pancreatic juice. Pawlow stated that the gastric acidity was the specific stimulant of the pancreatic juice. Boas recommended that in cases of achylia gastrica that acid be given to stimulate the pancreatic secretion. Boldyreff showed that if a large dose of oil was given into the stomach that a decided reflux of intestinal contents would occur into the stomach. Volhard from this devised the method of investigating the pancreatic secretion by giving 200 c.c. of oil and then removing the stomach contents in a half hour. The authors made use of this method in the present investigation, using either the Volhard oil test meal or Ewald's test breakfast on 98 patients. Fuld's method of ferment estimation was used. They also did some fistula experiments on dogs. Their conclusions are as follows: (1) Contrary to the previous belief in achlyia and anacidity, the pancreatic secretion is not injured, and is even greater than under normal conditions. (2) It is therefore unnecessary to give hydrochloric acid to stimulate pancreatic secretion. (3) This is further unnecessary because, according to the present experiments on dogs with pancreatic fistulæ, hydrochloric acid can no longer be considered as a specific stimulant for pancreatic secretion. (4) Following both Volhard's and Ewald's meals, trypsin can usually be found in the stomach in both achylia and anacidity. If repeated examinations are made it is always demonstrated. (5) In hyperacidity cases the oil breakfast usually fails to show trypsin. In other cases it is present only in traces, which may be increased by giving sodium bicarbonate. (6) Usually the quantity of trypsin varies directly with the amount of bile. (7) On the contrary, cases occur in which trypsin is absent in spite of an alkaline content rich in bile. (8) The cause of the failure or reduction in the amount of trypsin in the stomach in hyperacidity is apparently not alone its distruction by the acid, but is probably due to the absolute reduction of ferment secretion as observed by the authors, or possibly to the manner of action of the pylorus. (9) It has not been definitely proved in man that fat causes a physiological reflux of intestinal contents, as Boldyreff claimed in dogs, as mechanical actions, as the passing of the tube, strangling, and abdominal pressure, play an important rôle. (10) The method of estimating the pancreatic functions quantitatively by the reflux into the stomach is of little value. Complete loss of functional activity can, however, be proved in other ways. (11) When one wishes merely a qualitative estimation of trypsin in the stomach, probably the simpler Ewald test meal is more satisfactory, as one can make better comparisons with it.

The Occurrence of Spontaneous Cure of Brain Tumors.—Under this head Anton discusses the reasons for the apparent improvement in some cases of brain tumor. He suggests that this may be due to an adjustment of the circulation around a tumor which is not progressing. He then mentions the possibility of softening of the tumor itself. Aneurysm, gummata, and echinococcus cysts may recover. A tumor may become encapsulated or undergo cystic degeneration. Changes in the skull may reduce the pressure, as softening of the skull cap itself or erosions of the bone. The cerebrospinal fluid may escape through the nose or eyes. Lumbar puncture has been used extensively to reduce the pressure. This is sometimes followed by serious results in cases of brain tumor. A better method is puncture of the corpus collosum, as the author and v. Bramann have done it. This makes a permanent opening between the ventricle and the subdural space. The author raises the question whether the reduction of pressure may not increase the rapidity of growth of the tumor. This he thinks is not the case, but that the decreased pressure aids the resisting power of the normal nerve tissue and so reduces the progression of the tumor. He reports in full a case in point.

Tumor of the Hypophysis with Peculiar Visual Symptoms.—Crzellitzer describes a case of brain tumor. The patient was a light drinker and smoker. In January, 1908, he first noticed impairment of vision. In February the examination of the eyes was as follows: Bilaterally externally, loss of corneal reflex. Pupils equally dilated: right in dark 7 mm., in light 4 mm.; left, sluggish. Both optic nerves blue white on temporal sides. Arteries constricted; borders of the optic nerve indistinct. Maculæ normal. Vision O. D. 5-30, O. S. 5-50. Not improved by glasses. No astigmatism. Both visual fields slightly contracted. O. D. increased blind spot, for white; more so for red. Outer border of red normal. O. S. absolute central scotoma for all colors from 8° to 10°. The patient made no improvement on specific treatment. Later convergence paralysis appeared. An *x*-ray picture demonstrated a tumor in the region of the hypophysis. There were no symptoms of acromegaly and no glycosuria. The patient was still living at the time of the report. The author gives the literature of similar cases and discusses the cause of the symptoms.

Vasectomy of Criminals.—Indiana and Oregon have legalized the sterilization of criminals and other defectives in order to prevent procreation. In Indiana over 800 criminals have been operated on, 200 at their own request.

Hypodermoclysis with Artificial Oxygenated Serum in Typhoid Fever.—Agide Magi, after making use of oxygenated artificial serum in three cases of typhoid fever, recommends the use of this method of treatment. He finds that the subcutaneous injection of artificial serum produces a favorable influence on the circulatory system by increasing cardiac energy, raising blood pressure and regulating the pulse; assists the nervous system by general tonic action; increases the emunctory action of the skin and kidneys, producing diuresis and diaphoresis; lowers temperature, and acts favorably on the condition of intoxication of the system, increasing elimination of poisons by way of the urine, which increases in its toxicity. Artificial oxygenated serum used by hypodermoclysis in severe cases, and by enteroclysis in less severe ones, should occupy a high place as a therapeutic measure.—*Rivista Critica di Clinica Medica.*

Book Reviews.

THE OPHTHALMIC AND CUTANEOUS DIAGNOSIS OF TUBERCULOSIS. (The Cutaneous and Conjunctival Tuberculin Reactions According to v. Pirquet and Wolff-Eisner.) Together with a Discussion of the Clinical Methods for the Early Diagnosis of Pulmonary Tuberculosis. By Dr. ALFRED WOLFF-EISNER. A Preface by Prof. H. SENATOR and an Introductory Note to the English Reader. By C. THEODORE WILLIAMS, M.V.O., M.D., F.R.C.P., Consulting Physician to King Edward VII Sanatorium and the Brompton Hospital; Vice-President of the International Central Bureau for the Prevention of Consumption; Vice-Chairman of the National Association for the Prevention of Consumption. Translated from the German by BERNARD I. ROBERT. New York: William Wood & Co., 1908.

THE subject of the early diagnosis of tuberculosis is of such importance and interest that this small work should find a ready welcome in the library of every physician. It forms a complete review of the subject of local reaction tuberculin tests and contains much original work done by the author and his colleagues. A complete bibliography of over two hundred references, covering the work up to the time of publication, is appended.

Considerable space is given to a discussion of the theoretical and clinical values of the conjunctival and cutaneous tests, the author holding that the former test is largely of service in diagnostic work, while the cutaneous reaction furnishes a method upon which one may, with considerable accuracy, base a prognosis. He believes that if the reaction is prompt and marked after the application of a small amount of tuberculin there is indicated a strong resisting power in the body. On the other hand, "weak, rapid reactions, or even altogether negative ones, point to an unfavorable course of the disease." Inasmuch as clinically healthy individuals may react to both the conjunctival and cutaneous test, and as only positive reactions to very small doses of tuberculin appear to have much diagnostic importance, there still remains considerable to be done for the ascertainment of the real value of these tests.

Numerous charts showing the author's method of classifying and recording the results of local tuberculin tests are placed convenient for reference to the text. To Calmette has frequently been assigned the credit of originating the ophthalmo-tuberculin test, but Wolff-Eisner shows clearly in this work his own priority in suggesting its use clinically. The last section of the book, consisting of about fifty pages, is devoted to a thorough consideration of other methods of diagnosing pulmonary tuberculosis, and is deserving of the most careful perusal. Except for an apparent slight confusion as to the use of "tuberculous" and "tubercular," the translation from the German to the English text seems in every way to be satisfactory.

THE THEORY AND PRACTICE OF INFANT FEEDING. With Notes on Development. By HENRY DWIGHT CHAPIN, A.M., M.D., Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital; Attending Physician to the Post-Graduate, Willard Parker, and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital and to St. Agnes Hospital, White Plains. Third Edition, Revised. With Numerous Illustrations. New York: William Wood & Co., 1909.

THE present time marks a turning point in the theory and practice of feeding, for the so-called "percentage" method has been used long enough to allow a final judgment to be passed upon its merits. Due acknowledgment can be made to the progress which its introduction marked in the history of artificial feedinig; it has become quite evident, however, that mere adjustment by quantitative methods of the differences between cow's milk and breast milk is only a part of the problem. Experience has shown that a number of methods, condemned as unscientific according to the standards of the "percentage" method, are strictly in accord with biological laws of nutrition and are successful in practice. Dr. Chapin's book represents such judgment in the theory and practice of feeding, founded upon long experience in the subject and a critical study of the various steps in its progress. His book is really a treatise on nutrition in general, for he devotes a number of chapters to the biological processes occurring in the nutrition of animals, using these as an introduction to formulating a plan of rational artificial feeding of infants. The materials are then considered—that is, cow's milk, its bacteriology, preservation, methods of testing, and common adulterations. As illustrative examples are taken from actual examinations of milk sold in New York City, the chapters are intensely practical. Cereals, vegetable foods, proprietary foods, meats, and eggs are then considered. Dr. Chapin was among the first to point out the value of cereals in infant feeding, and his teaching in this branch of the subject has been amply proved correct by his experience and by the experience of his followers. Part III of the book is devoted to practical feeding, all the details in reference to breast feeding and to the preparation of artificial food mixtures being given. While general principles are stated, direct and clear descriptions of practical methods are given most attention, so that an intelligent nurse or mother can obtain all the information necessary for carrying on the nutrition of a child. Finally, feeding in disease, diet of older children, and the data of growth and development of infants are considered.

Throughout the book the author endeavors to show how the demands of science in the question of feeding may be realized with the materials and under the circumstances existing in modern city life. This makes the book a practical guide for all interested in the subject, whether physicians, nurses, parents, or students. To the latter, especially, the book is recommended, for, beyond serving as a text book, it will prove of great assistance in their early years of practice.

KRIEGSCHIRURGISCHE RÜCK- UND AUSBLICKE VOM ASIATISCHEN KRIEGSCHAUPLATZE. By Dr. HERMANN FISCHER, Professor of Surgery. Berlin: Hirschwald, 1909.

WHILE the reports of the various military observers with the Russian and Japanese armies in the recent war in Manchuria record in detail conditions as studied from their respective standpoints, this book of 200 pages discusses the medico-military aspects of the war as a whole from both sides. The book is well planned, complete in detail, clearly written and concise in expression. The experiences of the various observers have been freely drawn upon in its preparation, and the result is the most generally valuable single book available on sanitary organization, field hygiene, modern weapons of war, wounds and their treatment, aid stations and hospitals, and other matters important to the military surgeon.

PURE MILK AND THE PUBLIC HEALTH. A Manual of Milk and Dairy Inspection. By ARCHIBALD ROBINSON WARD, B.S.A., D.V.M., Assistant Professor of Bacteriology and Director of the State Hygienic Laboratory, University of California. With two chapters by MYER EDWARD JAFFA, M.S., Professor of Nutrition and Director of the State Food and Drug Laboratory, University of California. Ithaca, N. Y.: Taylor & Carpenter, 1909.

IN this manual the author has attempted to collect the main facts required for an intelligent understanding of the duties of milk and dairy inspectors. The book contains a large amount of cold fact, and numerous copies of Department of Agriculture "dairy score cards," requirements and directions of milk commissioners, details of analytical methods, and similar valuable material. The book takes up the common modes of contamination of milk at the farm and dairy, the diseases commonly carried by milk and the problem of bovine and human tuberculosis. The second half discusses the sanitary control of milk, bacteriological and chemical analytical methods, and the precaution in obtaining certified and Pasteurized milk for the market. Each statement is backed by its reference, so those wishing to look deeply into the subject of pure milk may find therein a very full bibliography. The book has its uses in this way. It is, however, written in a jerky style that renders it difficult to read consecutively. The slightly freer use of conjunctions and rearrangement of some sentences would improve its value. We notice, too, the frequent incorrect use of the word tubercular where the author means tuberculous.

THÉRAPEUTIQUE VÉNÉRIENNE. Par le Dr. M. DEGUY, ancien interne des Hôpitaux, ancien chef de laboratoire à la Faculté, Paris: G. Steinheil, 1909.

THE author premises at least a working knowledge of the pathology, symptomatology, diagnosis, and prognosis of venereal diseases and of some dermal infections. In a purely therapeutic sense, one-third of the book thoroughly presents the newest views regarding these affections. Deguy supports his statements with the results of personal experience. The remaining pages are devoted to two excellent chapters on laboratory researches, directed to the diagnosis of syphilis, in which the most modern methods, including ultramicroscopy, are discussed. Unfortunately, this new author does not bring us nearer the ability to make a positive diagnosis of the presence or absence of syphilis in a larger percentage of cases than did his predecessors. On the other hand, however, he clearly details the complete technique of all the methods; in doing so he emphasizes the hope that the time is not remote when lues will be as surely diagnozable as now are typhoid fever and diphtheria.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, Held at Atlantic City, N. J., June 8, 9, 10, and 11, 1909.

(Special Report to the MEDICAL RECORD.)

(*Continued from Vol. 75, p. 1125.*)

SECTION ON MEDICINE.

Thursday, June 10—Third Day.

Election of Officers.—*Chairman,* Dr. George Blumer of New Haven; *Secretary,* Dr. Wilder Tileston of Boston; *Delegate,* Dr. James Capps of Chicago; *Alternate,* Dr. Alexander Lambert of New York; *Orator,* Dr. Richard C. Cabot of Boston.

The Association of Aortic Insufficiency with Syphilitic Aortitis.—Dr. WARFIELD T. LONGCOPE of Philadelphia said that among 930 autopsies they had found 74 cases in which the aortic valves were sufficiently diseased to be noted as chronic aortic endocarditis in an anatomical diagnosis. They divided these cases into several groups. One, those in which the disease of the aortic valve was associated with lesions of the mitral or tricuspid valves. Secondly, those in which the aortic valve alone was affected. There were 20 cases of combined lesions, usually occurring in young persons with a history of rheumatic fever. In only three of these cases was there some calcification present. The second group again was divided into (1) those cases of chronic endocarditis associated with a peculiar type of cirrhosis; (2) those cases associated with other types of cirrhosis or in lesions of the aorta itself. Thirty-one cases of pure aortic endocarditis fell in this group and there was more or less thickening and stiffening, often calcification, of the aortic segments. Twenty-two cases were over fifty years of age. There were 20 cases with more or less thickening and curling of the valves, with retraction and without calcification and associated with a peculiar type of cirrhosis. All but four were under the age of 50. There were 14 males and six females. Fourteen were colored and six were white. Microscopically, the aorta was the seat of irregular pittings and corrugations, with occasionally soft semitranslucent patches of thickening. There was no calcification. Microscopically the intima presented various grades of thickening due to heaping up of cells of connective tissue type but there were no marked degenerative changes. In the media there were areas of necrosis. It was a matter of common knowledge that syphilis was a common cause of aortic insufficiency. Pure aortic insufficiency was rare after the fifth decade. It was seldom associated with the type of arteriosclerosis known as endarteritis deformans. The vast majority of the cases of pure aortic insufficiency were associated with a characteristic type of cirrhosis, mesarteritis. Syphilis was certainly the commonest cause although perhaps not the only cause of this type of cirrhosis.

DR. RICHARD C. CABOT of Boston said that some of these cases could now be recognized since the introduction of Wassermann's reaction. Some of these cases of aortic disease without any history of rheumatism or pyogenic infection, with a history of syphilis and with a positive Wassermann reaction in the blood responded to the antisyphilitic treatment even better than one would expect cases to respond when treated by rest, digitalis, purgation, and cardiac stimulants. Antisyphilitic treatment should be pushed in all cases of prolonged aortic diseases, especially where there was a history of syphilis and a positive Wassermann reaction.

DR. ALLEN A. JONES of Buffalo reported the case of a man, 46 years old, who had syphilis; shortly before death he gave positive Wassermann reaction but there were no evidences of aortic insufficiency. He had, however, three attacks of angina pectoris and died in the third attack.

Dr. Longcope said that he reported a case in which the patient had severe substernal pain and one or two attacks of angina. This was of course quite common in this type of cases because of syphilitic involvement of the coronary arteries.

Clinical Value of Recent Studies in Experimental Nephritis.—Dr. HENRY A. CHRISTIAN of Boston referred to the results of recent work in experimental nephritis. He did this, not because the results were of such great importance, but, because it seemed likely that the experimental method applied to the study of nephritis would throw much light on the problems connected with this disease. The phases of nephritis that were of clinical interest in man were the urinary changes, particularly the albuminuria and cylindruria, the uremia, the edema, the hypertension and associated cardiac hypertrophy, and finally the cause and cure. The consensus of opinion in regard to albuminuria was that the albumin of the urine, in a very large proportion of cases, came from the soluble proteins of the circulating blood and appeared in the urine as the results of pathologically increased permeability of the glomerular tuft. Degeneration of the epithelial cells might have a small part in producing this condition. In studying the origin of urinary casts produced experimentally, a variety of irritants such as cantharidin, corrosive sublimate, uranium nitrate, potassium chromate, when given to animals, would produce change in the kidney leading to the appearance of albumin and casts in the urine. Wallerstein concluded from his experiments that all casts were formed from degenerated, disintegrated, and metamorphosed tubular epithelium. Ribbery and Schlect, in studying the excretion of carmine through the kidney, had concluded that the hyaline casts were derived from the albumin excreted through the glomeruli, while the granular casts were derived from tubular epithelium. R. M. Smith had been investigating this subject at Harvard and had divided the irritants used into those which produced extensive changes of a degenerative character in the tubular epithelium, uranium nitrate, potassium chromate and mercuric chloride, and those which, while producing evidence of acute nephritis, produced comparatively slight changes in the tubular epithelium, such as cantharidin and arsenic. By varying the size, number, and intervals between doses of these various irritants, and by varying the length of the experiments, it had been possible very largely to control the lesions. It was found that the irritants which produced marked degenerative changes in the epithelium of the tubules gave rise to a more abundant cast formation than did the other group of irritants. Most casts were produced by those irritants which produced the most marked degenerative changes of the epithelium of the tubules. This indicated that there was a close association between changes of the epithelium of the tubules and cast formation. By studying histologically kidneys of animals receiving different irritants in varying doses cast formation could be traced morphologically. The first change seemed to be granular degeneration of the epithelium lining the distal convoluted tubules, which increased in severity until the epithelium became converted into a granular material. The current of fluid washed this granular material along the tubules into the lower levels of the tubules. In the early stages of the process urine analysis showed the presence of a number of casts, at first coarsely granular and later finely granular. With a longer interval and a less intense local process the casts became more hyaline in character. From a morphological point of view, supported by the results of urinary analysis, it seemed that both granular and hyaline casts in these animals arose from degenerative processes in the epithelium and that the

granular cases came earlier than the hyaline. These observations on animals were quite in harmony with the observed conditions in man. Attempts had been made to produce the condition analogous to uremia in man experimentally in animals but it could not be said that the studies in experimental nephritis had thrown much light upon the condition of uremia beyond giving support to the view that the condition was a toxic one with renal lesion. The relation of edema to nephritis had been the subject of much discussion and investigation, but even morphological studies had yielded no explanation of the occurrence of edema. In recent years physicochemical methods had been applied and special reference had been placed on salt retention with corresponding changes in osmotic tension. There was a growing skepticism toward salt retention as a primal cause of nephritic edema, though in many cases it might be a contributing factor, and the withholding of salt from the food might be therapeutically effective. There was increasing evidence to show that peripheral vascular lesions played a large role in the production of edema. The experiments of Heineke, Meyerstein, and Blanck, though not constant in their results, were very suggestive of the importance of the rôle of circulating toxic substances in the blood in nephritic edema. Some of the theories advanced for the hypertension and associated cardiac hypertrophy of chronic nephritis had been submitted to experimental test. A critical review of this work showed that results had been very inconstant. One group of observers believed that the internal secretion of the kidney was a factor in raising the blood pressure but the experimental work seemed to indicate that at the present time no very great amount of importance could be attached to the internal secretion of the kidney as a factor in causing hypertension. In a number of experimentally produced chronic renal lesions there was evidence of cardiac hypertrophy. Since the various experiments suggested that they could experimentally control the production of cardiac hypertrophy and obtain the result by producing chronic renal lesions, chronic myocardial lesions and chronic vascular lesions, it might be possible by such studies to arrive at the causal factor which acted chiefly in any one of these types.

The Causes of Hypertension in Nephritis.—Dr. John H. Musser of Philadelphia stated that one had no exact knowledge of the causes of hypertension in nephritis. The theories elaborated had been mostly based on clinical observations. While neither the clinical experience nor the experimental evidence was at all conclusive, each in its way pointed to an explanation through the action of some chemical substance influencing the circulatory system. What this substance might be or how it acted they did not know. Hypertension like uremia was an evidence of renal insufficiency. It was naturally suggested that the poison of uremia was identical with that causing hypertension, or, if different, it was formed at the same time and was due to the same causes, or possibly one was the derivative of the other. If there was but one poison it was possible to conceive that in small amounts it affected the vasomotor apparatus and in large amounts exerted a toxic effect on the nervous system, producing uremia. This chemical theory was supported by the frequent clinical experience that the degree of the uremic manifestations and the recovery from these had a close relation to the blood pressure. Moreover, true uremia without hypertension seldom occurred. In connection with this chemical or retention theory the effects of diet were suggestive. Experiment had shown that rich protein diet increased the tension and disturbed the general condition for the worse. This probably meant a retention of the products of nitrogenous metabolism and possibly of that nitrogen which in the urinary partition was known as undetermined nitrogen. The increase of these substances in the blood of that group of renal diseases in which uremia occurred suggested that they might be the cause of uremia and that they might also be the substances responsible for increased tension. There was nothing at present to add to this view that hypertension was to be explained by retained products of metabolism. Dr. Musser thought that the theory in regard to the internal secretion of the kidney could be dismissed. A closely related theory was that which assumed a correlation between the kidney of chronic interstitial nephritis and the secretion of the adrenal. French investigators had described a localized or diffuse hyperplasia of the adrenals accompanying chronic nephritis in those cases which did not run too rapid a course. This hyperplasia was considered as an indication of the functions of the gland. This theory had a relation also to the arteriosclerosis associated so constantly with the interstitial type of nephritis. As reports multiplied and the lesions were found in other conditions the importance of the observation diminished. The attempts to demonstrate adrenalin or adrenalin-like bodies in the serum of nephritis was also of interest in this connection but more evidence would have to accumulate before the observations made could be of any value. The chief difficulty in explaining hypertension in chronic interstitial nephritis was the almost constant presence of arteriosclerosis. It was a question whether the kidney injury was primary and led to arteriosclerosis or whether a poison first affected the blood vessels and the kidneys secondarily through the disease of their own arteries. The latter view seemed to be the one gaining adherents. However, many poisons might simultaneously affect both the kidneys and the vascular system. The study of renal disease following infectious diseases threw some light upon this subject. Here hypertension appeared to be primary and the heart hypertrophy and arteriosclerosis secondary. In scarlatinal nephritis hypertension came on very early and the only explanation that could be offered was that of increased peripheral resistance, a contraction of the arterial terminals. This contraction was the result of some chemical influence but again they were brought back to the theories just discussed as concerning which they had come to no definite conclusion. There was an important field for investigation. First as to the tension in various forms of epithelial lesions and secondly, a cooperation between the clinician and the pathologist as to the relation of hypertension to histological changes, with special regard to the glomeruli. Experiments definitely demonstrated that the high pressure associated with glomerular lesions could not be explained by the earlier theory of diminution of vascular territory in the kidney. Loeb offered as a hypothesis, that since the renal activity varied directly with the blood supply, lesions of the glomeruli would limit local vasodilation. When the renal activity demanded more than the local conditions allowed, the stimulus went beyond the kidney and exerted reflexly a splanchnic contraction which led to an increased flow of blood through the glomeruli. This theory brought out the fact that hypertension, be its cause what it might, was essentially a conservative process having for its object the maximum functioning power of the kidney. Passler and Heineke, by reducing the kidney substance in animals by successive excisions, had concluded that in the state of renal insufficiency thus produced the heart hypertrophy was due to the increased work resulting from the tendency to arterial spasm and that this in turn was due to the effect of retained toxic substances. This again brought them back to the chemical theory of retention, but they knew nothing of the substances retained, and here was the problem of the cause of hypertension in nephritis, a problem that could only be solved by methods of chemistry and physiology assisted by clinical observation.

The Value and Limitations of Salt-Free Diet and Restriction of Fluids in Nephritis.—Dr. Victor C.

Vaughan of Ann Arbor presented this paper. The following points seemed to be fairly well established. (1) Urea and uric acid were not important constituents of the urine so far as their toxicity was concerned. (2) About 85 per cent. of the toxicity of the urine was due to its inorganic constituents, the most toxic of which was potassium chloride. (3) There were present in normal urine certain organic poisons, the nature of which had not yet been ascertained. (4) Although the inorganic constituents, notably potassium chloride, were markedly poisonous, they could not be regarded as a direct causal relation to that complex of symptoms which they designated as uremia. He felt confident that in withholding salts from their nephritics they were not withholding the direct cause of uremia. The best that they could hope for in the use of a salt free diet was to protect the kidneys by decreasing their labor and thus conserving their capacity as organs of elimination. The inorganic salts were not, singly or combined, the active and direct cause of uremia. There were reasons for suspecting not only that the inorganic constituents in the urine were in part neutralized by the organism, but also in part by one another. It was quite evident that poisoning due to the retention of normal constituents of the urine and uremia were two quite distinct and different things. A point he wished to emphasize was that poisoning from anuria and uremia were two distinct things, and while the inorganic salts were the most poisonous constituents of the urine, their retention in the body could not be regarded as the cause of uremia, certainly not the direct cause. It was suggested by Widal in 1903 that nephritic edema was due to chloride retention, that with the disappearance of the edema the elimination of chloride was increased, and that the proper treatment of the edema of nephritis should provide a diet that was largely salt free. The reports, however, of clinicians had not been so satisfactory. There was some clinical evidence that edema did increase the danger of uremia. At least uremic symptoms had been seen to disappear with the disappearance of the edema and to return with the accumulation of fluid in the tissues. However, there was a causal relation between edema and uremia, because the latter was frequently seen in interstitial nephritis when the former was absent or but slightly developed. Edema in nephritis was due to diverse causes, and certainly not always due to salt retention.

Management of Uremia.—Dr. Edward F. Wells of Chicago read this paper and said that for the purposes of this discussion uremia might be tentatively defined as an auto-intoxication, which affected mainly the nervous system, and occurred in connection with renal insufficiency. It was due to the retention in the blood, tissue, lymph, and cells of the body of certain indeterminate, but specific, products of perverted, or normal, tissue metabolism, which were not excreted by the inadequate kidneys, were not taken up by the lymphatic radicles, or were not neutralized or destroyed by the lymphatic glands or other protective organs. He confined himself to a consideration of some of the problems in the management of uremia, with particular reference to the disturbances of the intra- and extravascular circulation, in that protean malady known technically as chronic interstitial nephritis. Upon making a diagnosis of chronic interstitial nephritis the physician should make earnest efforts towards preventing the development, or recurrence of recognizable uremia. The diet should be so arranged along the established lines, as to maintain nutritive equilibrium at the highest possible level, with the smallest total amount of protein and carbohydrate foods. The total liquids should be so adjusted as to carry off the largest amount of excrementitious materials. The regimen should consider such important matters as residence, clothing, occupation, exercises, environment, etc. The amount and character of the physical exercises should be adjusted to meet the varying capacity and requirements. Extraordinary care should be made to avoid infectious diseases. Ordinarily the high tension was conservative and should not be interfered with. When there was a sudden exaltation of tension, with the patient in great distress, the best interests were served by anticipating the near-inevitable by artificially lowering the excessive pressure. The uremia of the cardionephritic dropsical patient was due to vital, and not to mere mechanical, disturbances. It was significant that the serum obtained from the liquid bowel movements of such nephritic patients had been much heavier laden with chlorides, and often with sulphates too, than in others with pure cardiac dropsies. Edema interfered greatly with the composition of the blood and the extravascular lymph, and with cellular nutrition. The capillaries and lymphatic radicles were compressed, with interference with their function; the tissue lymph became stagnant and laden with specific toxins and tissue waste materials; the extravascular circulation was short-circuited. During the first day the diet should consist of thin gruels, cream and water, vegetable soups, tea, coffee, cocoa, water, and carbonated waters. From these there should be omitted the gruels on the second, and the soups on the third day; during the fourth and fifth days very little should be taken; on the sixth day the soups should be replaced, and on the seventh day the gruels; later the ordinary careful dietary of the nephritic should be gradually resumed. Every night of the first three days the patient should take 10 grains of mercurial mass, in two recently made pills of 5 grains each, followed by an efficient dose of sodium or magnesium saline in the morning. Beginning on the fourth morning, after free action of the saline, there should be given 1/30 grain of pure elaterin hourly for three doses; 1/24 grain every two hours for three doses; finally 1/18 grain every three hours until ten or twelve copious watery bowel movements have been induced. During the time the elaterin is being given the patient should remain in bed. He should be informed of the abdominal distress, nausea, and vomiting which the drug sometimes induced.

Dr. David L. Edsall of Philadelphia said that it was quite clear from what had been stated in the papers regarding the chloride-free diet that many erroneous conclusions had been reached. For various reasons the theories regarding the important relation of the chloride-free diet and the edema were not at all established; there were many reasons for thinking that the conclusions reached were erroneous. Whatever one might think regarding the relation of salt to the symptoms of nephritis it was clearly a valuable procedure to limit strictly the amount of certain substances, and particularly table salt. A great deal of good could be given by more attention to the diet of these patients. In the treatment of uremia of persistent form, attended by a state of high tension and circulatory failure, with the patient in a very bad state rebelling against everything, he believed in actual starvation. The kidneys should be relieved as much as posible for a brief period.

Dr. De Lancey Rochester of Buffalo commended the treatment of uremia as outlined by Dr. Wells but, in addition, there was one thing of great value, namely, the consideration of the skin as an eliminative organ. Profuse sweating did much good and was easily produced by giving minute doses of pilocarpine about ten or fifteen minutes before giving the hot bath or pack. Of great value in these cases was the use of small doses of elaterium twice daily.

Dr. James Tyson of Philadelphia said that it was a matter of clinical experience to find hyaline casts first, and not the granular casts. Not enough stress had been laid upon the treatment of the hypertrophy and the high tension *per se*. One should strike at the root of the evil and

remove the cause of the high tension. It was difficult to have the starvation treatment, as referred to by Dr. Edsall, properly carried out. Twenty years ago they treated the nephritides with small does of milk, giving as little food as possible. Where it seemed desirable to give nourishment one should not give large quantities of milk, but small quantities of diluted milk.

Dr. John A. Licity of Pittsburg reported some interesting cases. One man, twenty-four years old, had a severe form of nephritis following an attack of scarlet fever, and had been consulting regarding it with Dr. Tyson of Philadelphia and Dr. Janeway of New York. The albumin and casts remained in his urine year after year. An interval operation for appendicitis was decided upon as being necessary; this was done and without any disturbance in the urinary excretion at all. Another patient had diphtheria followed by general anasarca. Dr. Osler saw this case, a very severe one. This patient also had to be operated upon and the ether narcosis had no effect upon the kidneys. He saw another case with a colleague; the amount of urine passed was supposed to be normal and the kidneys as well; yet after an operation there was a shower of casts and albumin, together with an acidosis, and the patient died within twenty-four hours. With this experience in mind it seemed to him that after all their knowledge of this condition, so far as it came down to the individual, was not very extensive.

Dr. John N. Upshur of Richmond, Va., entered a protest against the administration of morphine or any opiate as a temporary palliative in the treatment of uremia. One should test the kidneys and at the same time increase elimination; in this way they would accomplish more than if they got their heads in the bushes by giving morphine, thinking they were accomplishing something.

Dr. C. W. Smith of Baltimore said that the papers and discussion showed what had been done in experimental medicine which was corroborated by clinical observation; these were the only two measures by which they were to secure progress in the treatment of this affection, or in fact, in the treatment of any other. He was glad to hear mentioned the importance as an etiological factor of vascular disease in these cases of edema, and the benefit to be derived from actual starvation. No bad results had ever followed two days actual starvation in these cases with edema.

Dr. Boardman Reed of Los Angeles, Cal., said that fasting or starvation was of value not only in nephritic conditions with edema, but also in other affections; they all knew that in gastric ulcer and cases of hyperchlorhydria starvation or very light diet was of considerable value, particularly when there was high tension.

Dr. Hugo A. Freund of Detroit condemned the desultory use of the sphygmograph; if this instrument was properly used in many cases an oncoming uremia could be foretold long before the convulsions or gastrointestinal disturbances made their appearance. The sphygmographic tracings carefully studied would give far better indications for treatment and would give better results than were obtained in the haphazard way.

Operative Treatment of Cirrhosis of the Liver.—Dr. George Dock of New Orleans said that the statistics of the Talma-Morison operation and its modifications and substitutes were unfavorable partly because many cases had been operated upon too late to do good, and when the risk of death was excessively great on account of other organic diseases. The death rate and the shortening of life must not be compared with similar incidents in persons previously healthy, or persons with trivial diseases. As in so many borderline cases, they should think chiefly of the pain and disability, and the inevitable death within a time not very long, under the usual methods of treatment. From that standpoint a single patient made comfortable for a time beyond the usual expectations, outweighed many others whose days might have been lessened, though they lost nothing they ever could have gained in function. In such a case the matter should be put as plainly as possible before the patient, and he should decide. Many would prefer the cathartic and trocar; some, however, would prefer a definite risk with the hope of relief. He had found one case that seemed an ideal subject, a man with recently developed ascites and distinct but not severe symptoms of cirrhosis, no cachexia, and no anomalies in the urine. Paracentesis gave no characteristic fluid and showed the liver not enlarged. This patient chose operation which was performed by an experienced surgeon. The liver was moderately cirrhotic, the spleen enlarged, the veins in the omentum and under the parietal peritoneum were distended. Death occurred on the third day from septic peritonitis. Such an event was discouraging, but it gave him all the greater pleasure to report another case in which the duration of life and maintenance of function seemed unmistakably lengthened, notwithstanding many adverse circumstances. A brief summary was as follows: The patient had symptoms of cirrhosis of the liver, with ascites, following a history of hard work and hard drinking; he was tapped for the ascites fourteen times, and then an omentopexy was performed in December, 1902; he was tapped ten times after that, up to June, 1903, and since that time had been able to do hard work, only at long intervals having symptoms, which were easily relieved by medicine. Dr. Dock was inclined to agree with Rolleston in attributing the benefit chiefly to the lessening of venous pressure, enabling the liver to deal more readily with the toxic substances passing through it, the improved circulation following the reduction of venous pressure, and the greater chance of compensatory hyperplasia.

Report of the Committee on the Revision of the Pharmacopeia.—Dr. Thomas McCrae presented this report of the committee which was composed of Drs. Joseph A. Capps of Chicago, Joseph H. Pratt of Boston, Thomas McCrae of Baltimore, and John T. Halsey of New Orleans. It had not been the aim of this committee to do more than to bring forward what seemed to be the changes which might advisably be made in the revision of the pharmacopeia from the standpoint of the clinician. An important point which should be kept in mind was the possibility of making the pharmacopeia something which would come into constant use by the members of the profession generally. In bringing this about one important thing was the reduction in size, which seemed to be a point worth considering. Might it not be possible to omit the appendix? Another point was in regard to the publication of an annual bulletin. Another point was as to the advisability of introducing any substance "which cannot be produced otherwise than under a patented process or which is protected by proprietary rights." The advisability of doing this had been hinted at in the eighth pharmacopeia. The committee felt that this would be a mistake and that the position taken in the last pharmacopeia should be maintained. The following was a partial list of the drugs the committees thought should be dropped: Acetum opii, acidum camphoricum, aconitina, adeps, althea, anthemis, berberis, calamus, calendula, cassia fistula, chimaphila, chirata, cimicifuga, cinchonidinae sulphas, cinchoninae sulphas, cypripedium, euonymus, eupatorium, frangula, gambir, geranium, hedeoma, krameria, lappa, limimentum saponis mollis, marrubium, matico, matricaria, mezereum, oleum coriandri, oleum erigerontis, oleum sabinae, oleum sinapis volatile, pareira, phytolacca, pimenta, piperina, pulvis acetanilidi compositus, quillaja, rhus glabra, rubus, sabal, safrolum, scutellaria, staphisagria, unguntum potassii iodidi, unguentum zinci stearatis, unguentum hydrargyri, unguentum hydrargyri dilutum, and xanthoxylum. Regarding the drugs which should be added, the

following seemed worthy of consideration: Calcium lactate, phenolphthalein, arsenic (the value of sodium cacodylate and sodium aminophenyl arsenate hypodermically seem definitely established), theobromine, bile salts, diacetyl-morphine, and theobromine-sodio-salicylate. There seemed to be good ground for the feeling that they should go slowly in adding to what had been too voluminous already.

Dr. M. I. Wilbert of Philadelphia said that there was no question but that physicians should be the dictators regarding the omissions and admissions of drugs to the pharmacopeia; that was their province; it was their duty. They should dictate just what this book should contain. At the same time the clinician did not require reprentation on the revision committee; there was nothing in connection with the revision committee of direct interest to him or to which he could materially contribute. The clinician hampered their work. Much was said regarding the size of the pharmacopeia; the committee believed that it could be divided with benefit into two halves, one of which would appeal to the medical man, whereas the total would be necessary to the pharmacist. There was now very much in the appendix that was absolutely of no interest to the medical practitioner; again there was much material in the pharmacopeia which could be relegated to the appendix.

Dr. L. A. Conner of New York believed that the pharmacopeia as it existed to-day did not entirely meet the needs of physicians. The question arose, how could it be made to meet their needs more adequately. A volume not one-third the size of the present one would serve them well. Dr. Conner believed that the whole matter of the introduction of new drugs should be properly in the hands of the Council on Pharmacy and Chemistry. This Council might publish yearly or frequent bulletins to aid them in the selection of comparatively new drugs. They much preferred not to use drugs that were patented; but it seemed perfectly obvious that many patented drugs were used, would be and should be used.

Dr. John F. Anderson of Washington believed that in the list should be included the tetanus antitoxin; its value as a prophylactic entitled it to admission to the pharmacopeia.

Dr. W. Clayton Thrush of Philadelphia said that preparations of the adrenal gland was supplied by different firms under different names and that it would be well to have them admitted under one name; they all consisted of a 1-1,000 strength in physiological saline solution.

Rocky Mountain Spotted Fever.—Dr. H. T. Ricketts of Chicago showed by means of lantern slides the geographical distribution of this disease and called attention to its epidemiological features and their correspondence with the life cycle and habits of the tick.

Dr. Woods Hutchinson of New York spoke of the great variation in the virulence of this disease as he had met with it on the Pacific Coast: in Montana there was a high mortality, as well as in Idaho, whereas in the eastern part of Oregon it appeared as a mild infection, the vast majority of the cases ending in recovery.

Algid Malarial Fever, with Report of Cases.—Dr. Thomas D. Coleman of Augusta, Ga., read this paper. He said the pernicious types of malarial fever were of absorbing interest because of their diverse clinical features and their high mortality. From his study of the classification of others and from his own experience with this type of disease he thought that a subdivision into the comatose, hemorrhagic, and algid varieties was all that was needed for accuracy and elasticity. He had seen no variety that could not be placed under one of these subdivisions. A multiplication of them was therefore, not only confusing but unnecessary. It was generally conceded that pernicious malaria was produced by the action of the estivoautumnal variety of the *Plasmodium malariæ;* why then were some of the cases produced by them mild or malignant and others severe or pernicious? Unfortunately one must depend here upon reasoning from analogy and from one's knowledge of the life history of the parasite. First, one might assume that the number of the invading parasites with the toxins secreted by them was sufficient to bring about the pernicious symptoms. Against this it might be argued that in many fatal cases few parasites had been found. In such cases it might be, and likely was, that the parasites had collected in the internal organs. Secondly, it might be argued that either the parasites possessed an unusual virulence or that the resisting power of the individual had been lessened by preceding attacks of this or some other disease, or some vice of constitution. Thirdly, it might be supposed that the parasites for reasons unknown tended to accumulate in some portion of the anatomy, interfering with the circulation there and causing greater absorption of their toxins at the point of attack. It might be that some or all of these factors were operative. Algid malaria might be defined as a pernicious type of malaria, caused by the estivoautumnal form of *Plasmodium malariæ,* and characterized by profound prostration, cold and clammy skin, and an unclouded intellect. This disease occurred in all tropical and subtropical countries where malaria was found. Its pathology did not differ in any essential particulars from that of other forms of pernicious malaria, with the single exception of hemorrhagic malaria, in which the urine was more or less surcharged with hemoglobin, giving to it the name of "black-water fever." The symptoms were clear cut and definite, and from them it got its name algid malaria. The prognosis was usually grave and, in his experience, the mortality was 100 per cent.

Dr. John A. Witherspoon of Nashville said that the cases reported by Dr. Coleman were those in which the patient was overwhelmed by the toxemia of malaria. The cases described by him with choleraic diarrhea, nausea, vomiting, rice water discharges, purging, etc., were fortunately rare. He had seen only two cases of the type described by Dr. Coleman; one patient died one hour after he reached the bedside; the other thirty-six hours after. They both died of an overwhelming toxemia. There was evidently little to be done for such cases. The only hope was in artificial heat, saline irrigations, and transfusions and injections. The hypodermic injection of solutions of quinine, injected deeply, which gave good results in other forms of malaria, was practically useless; the only hope for benefit in these cases he believed to be in the intravenous introduction of quinine. That was the only way to reach the toxemia, and considerable sized doses should be used. In most cases fifteen or twenty grains was sufficient, although he had used as high as 140 grains in three hours. He was glad to report that malaria in the south was being materially lessened.

Dr. James B. McElroy of Memphis, Tenn., believed that the best classification was the one mentioned by Dr. Coleman, the comatose, algid, and hemorrhagic forms. There were the pernicious paroxysms occurring every five or six hours in conformity with what was known regarding the cycle of the parasite; the behavior of the parasites in the so-called "black-water fever" was entirely different from what was seen in the ordinary forms of pernicious malaria; when the blood was examined twenty-four hours after the onset, hemoglobinuria was seldom or never found; therefore, he thought the so-called black-water fever should be excluded from the hemorrhagic group.

The Value of Alimentary Levulosuria in the Diagnosis of Hepatic Cirrhosis.—Dr. Edward H. Goodman of Philadelphia read this paper and concluded as follows: (1) Alimentary levulosuria was almost a constant phenomenon in cirrhosis of the liver. (2) The early or late

appearance of levulose might be regarded as a sign of severe or mild hepatic disease. (3) Alimentary levulosuria was a useful aid in diagnosing between cirrhosis on the one hand and chronic passive congestion on the other. (4) In addition to levulose, a study of the hepatic function with glucose and with saccharose was to be desired, inasmuch as there might be an individual intolerance to carbohydrates. (5) While not indicative of any specific organic lesion of the liver, alimentary levulosuria was most frequently observed in cirrhosis.

The Nature and Treatment of Anemia.—Dr. S. P. Beebe and Dr. W. Gilman Thompson of New York called attention to the studies in metabolism which had been made on patients suffering from pernicious anemia, and gave the results of these studies, particularly with reference to the nitrogenous metabolism. In the idiopathic form (not referring to those conditions which could be explained by intestinal infections) they found that good hygiene, fresh air, abundance of good food, and rest were very important factors. They had found that in this condition there was no secretion of hydrochloric acid, or, if any, very little. Digestion could be improved, both in the stomach and intestines, by the administration of hydrochloric acid, and their best results were obtained from considerable quantities, not ten or fifteen drops of the diluted acid, but a solution of such concentration as would approach that contained in the normal gastric juice. Arsenic in its various forms had been tried. No benefit at all was derived from the use of iron in any form.

Dr. De Lancey Rochester of Buffalo reported a case of pernicious anemia which improved under the use of Fowler's solution and apparently recovered; eighteen months later he had a relapse, and again apparently got well; he finally died of pernicious anemia as the autopsy showed.

Dr. Theodore Potter of Indianapolis said there was great difficulty in judging of the value of the various forms of treatment recommended in this disease; improvement very often followed, but sooner or later, under any treatment so far advocated, the patients succumbed to the disease.

Dr. Louis G. Heyn of Cincinnati spoke of prohibiting the use of nitrogenous foods; if given they were apt to undergo putrefactive changes in the bowels. He could see benefit from the use of hydrochloric acid given in large quantities in aiding digestion.

Dr. Joseph L. Miller of Chicago called attention to the danger of using large doses of arsenic subcutaneously; very often there was caused an optic neuritis.

Dr. Walter J. Bjerring of Iowa City, Ia., said that one year ago he had reported a series of cases of pernicious anemia and in none of them was the free hydrochloric acid anywhere near the normal limit; these patients apparently improved under the use of arsenic, colonic irrigations, careful feeding, and various remedies; but in reality nothing had any effect upon the course of the disease. All the patients he reported then were dead.

Dr. S. P. Beebe of New York said he did not intend to give the impression that the administration of hydrochloric acid cured these patients; that was very far from the meaning he wished to convey. At the same time he did believe that a considerable number of these patients would be improved by it. Attention to hygiene often gave as good results as did the giving of medicines; he emphasized the importance of fresh air, good food, rest, etc. With regard to nitrogenous metabolism in these cases he thought they were justified in saying that metabolism was nearly normal; they had not been able to find any abnormality about the nitrogen in the urine.

The Work of a Cooperative Hydrotherapeutic Establishment.—Dr. Joseph H. Pratt of Boston called attention to the neglect of scientific hydrotherapy in America and the lack of instruction in the subject in the medical schools. A noncommercial hydrotherapeutic institution had been established in Boston, and he told of its influence in advancing physical therapeutics in that locality. He gave the results of his observations and studies carried on in the Boston establishment.

Dr. John A. Lichty of Pittsburg believed that such an institution was a very necessary adjunct to the therapeutic armamentarium. If the physicians would not take this matter up the quack would, and with great harm to the patients. He reported a case of a patient with loss of cardiac compensation, enlarged liver, etc., who was treated by massage and exercises with serious results in the endeavor to reduce the size of the enlarged liver. Physicians should protect themselves, and unless they established such institutions they were at the mercy of these people. He was glad to report that such an institution was about to be opened in Pittsburg.

Dr. C. W. Smith of Baltimore said that Dr. Pratt's work in Boston was well known and appreciated throughout New England. He called attention to a class of cases that was particularly adapted to this form of treatment, namely, vasomotor conditions with a neurotic etiology and vasomotor conditions arising from cardiac diseases, so often seen in young boys and girls; they were quickly relieved by hydrotherapeutic measures, but little benefit followed the use of drugs in these cases; but they could be very satisfactorily treated by sanitary measures, an open air life, proper diet, and hydrotherapy.

Dr. Andrew MacFarlane of Albany, N. Y., said the first duty of the physician was to cure his patient, and the way to do that was first to learn the cause of his trouble and remove it. That, however, did not appeal to the popular mind. The medical profession did not appreciate the value of physical therapy; they relied too much upon the giving of prescriptions. He thought it was a disgrace to the medical profession that an ex-prize fighter should be able to make a success of a sanatorium in the State of New York, a sanatorium which attracted not the ignorant, but the most intelligent men in the United States; it seemed that this man could do what the scientific medical profession could not do.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, State of Georgia.

Augusta, Ga., May 3 and 4, 1909.

ANATOMY.

1. Name articulations of occipital bone.
2. With what bones does the clavicle articulate?
3. What bones make up the pelvis?
4. Name bones of tarsus.
5. What muscles form quadriceps extensor, and where is its conjoined tendon inserted?
6. What muscles comprise pectoral group?
7. Give origin and insertion of pectoralis major muscle.
8. What blood-vessels pass to and from liver?
9. Name branches of external carotid artery.
10. Name branch of femoral artery.
11. How is circle of Willis formed?
12. In anatomy of brain what is corpus callosum?
13. Give origin and exit of pneumogastric nerve.
14. Give origin and exit of trifacial nerve.
15. What is contained in middle mediastinum?
16. Name subdivisions of alimentary canal.
17. Where in the topography of the abdomen is the sigmoid flexure? The appendix?
18. Into what and how far from the pyloric orifice of the stomach does the ductus communis choledochus open?

PHYSIOLOGY.

1. What four elements do all quaternary proximate principles contain? Practically into what must albuminoids be changed before absorption?

2. Name the intestinal glands. Tell where each variety is situated. What do they secrete and name the ferments.
3. Describe the renal circulation.
4. Give the chemistry of respiration.
5. Give origin and function of the hypoglossal nerve.

CHEMISTRY.

1. Give tests by which mercuric compounds can be distinguished from mercurous compounds.
2. Give the chemical and pharmaceutical names and formulas of two preparations of sodium.
3. What are leucomains? Antitoxins?
4. Give a chemical and physiological antidote for morphine. Explain action of each.
5. What is the normal reaction of pancreatic juice, and to what is it due? Of gastric juice? To what is it due?

MATERIA MEDICA AND THERAPEUTICS.

1. Give classification of medicines with definition, and example of each group in their alphabetical order.
2. Veratrum viride: Preparations, physiological action, therapy.
3. Gelsemium: Preparations, physiological action, therapy.
4. Opium: Preparations, its six principal alkaloids; official preparations of morphine; treatment of acute poisoning.
5. Salol: Definition, physiological action, therapy.

PATHOLOGY.

1. Describe the pathological changes in the three stages of acute lobar pneumonitis.
2. What pathological changes occur in the air-cells during pulmonary hepatization?
3. Give the morbid anatomy in acute yellow atrophy of the liver.
4. (*a*) What is productive inflammation? (*b*) What is suppurative inflammation?
5. Describe fatty degeneration as distinguished from fatty infiltration of tissue.

PRACTICE OF MEDICINE.

1. Acute articular rheumatism: Definition, etiology, morbid anatomy, symptoms, complications, diagnosis, treatment.
2. Cholera asiatica: Definition, etiology, morbid anatomy, symptoms, complications and sequelæ, diagnosis, prophylaxis, treatment.
3. Dysentery: Definition, etiology, clinical forms, anatomy of each form, diagnosis, treatment.
4. Hydrophobia: Definition, pathology, symptoms, diagnosis, prognosis, treatment.
5. Uncinariasis: Definition, etiology, pathology, diagnosis, treatment.

OBSTETRICS.

1. What attention should be given to the kidneys of pregnant women?
2. What are the symptoms of threatened eclampsia?
3. What are the causes of antepartum hemorrhage? How should they be managed?
4. What is the usual procedure in the delivery of the placenta?
5. How would you manage a breech presentation?

PEDIATRICS.

1. Give etiology, complications, and duration of pertussis.
2. Give treatment of acute adenitis.
3. Define ophthalmia neonatorum and give its treatment.
4. Give synonym and treatment of scabies.
5. Give diagnosis and treatment of bronchopneumonia.

GYNECOLOGY.

1. Define endometritis, and give its causes, varieties, and treatment.
2. Give a differential diagnosis between ovaritis and ovaralgia.
3. Give the pathology of (*a*) hydrosalpinx, (*b*) hematosalpinx; give the diagnosis and treatment of each.
4. Is ventrofixation of the uterus justifiable? If so, state under what circumstances, and describe the operation.
5. What is the menopause, and in what manner would you explain the theory that it is a critical period in a woman's life?

SURGERY.

1. Define abscess; aneurysm. With what condition may aneurysm be confounded?
2. Make briefly a diagnosis of coma from injury, apoplexy, uremia, opium poisoning, and alcoholic intoxication.
3. Define peritonitis.
4. State two or more ways in which the peritoneum may be invaded by bacteria.
5. What are the contraindications respectively to the use of the three principal anesthetics—nitrous oxide, ether, chloroform?
6. What is dislocation? Fracture?
7. Give differential diagnosis between fracture and dislocation.
8. Describe Colles' fracture.
9. Outline treatment of same.
10. What is hemorrhage?
11. How would you arrest epistaxis?
12. Describe operation for ligation of subclavian artery in its third portion.
13. What arteries require ligating in amputation, at middle third of leg?
14. Describe complete indirect inguinal hernia.
15. Give symptoms of strangulation, methods of reduction, and operation if strangulation exists.
16. Describe an approved operation for the radical cure of oblique inguinal hernia.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF GEORGIA.

Augusta, Ga., May 3 and 4, 1909.

ANATOMY.

1. The *occipitol bone articulates* with:—two parietals, two temporals, atlas, and sphenoid.
2. The *clavicle articulates* with:—sternum, scapula, and cartilage of first rib.
3. The *bones which make up the pelvis* are:—Two ossa innominata (each composed of the ilium, ischium, and pubis), sacrum, and coccyx.
4. The *bones of the tarsus* are:—The os calcis, astragalus, cuboid, scaphoid, and internal, middle, and external cuneiform.
5. The *muscles which form the quadriceps extensor* are:—Vastus externus, vastus internus, rectus femoris, and crureus. It is inserted into the tuberosity of the tibia (it is sometimes described as being inserted into the patella).
6. The *muscles of the pectoral group* are:—Pectoralis major, pectoralis minor, subclavius, and serratus magnus.
7. PECTORALIS MAJOR. *Origin*:—Anterior surface of inner half of clavicle, anterior surface of sternum, from the cartilages of the second to sixth ribs, and from the aponeurosis of the external oblique of the abdomen. *Insertion*:—Into the outer bicipital ridge of the humerus.
8. *To* the liver, there pass the hepatic artery, and the portal vein; *from* the liver, pass the hepatic veins.
9. The *branches of the external carotid artery* are:—Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary.
10. The *branches of the femoral artery* are.—Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, muscular, anastomotica magna, and profunda femoris (with branches: external circumflex, internal circumflex, and three perforating).
11. The *Circle of Willis* is formed:—In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.
12. The corpus callosum is the great transverse commissure, which lies at the bottom of the great longitudinal fissure, and connects the two cerebral hemispheres.
13. PNEUMOGASTRIC NERVE. *Origin*:—(1) *Superficial*, from the groove between the olivary and restiform bodies; (2) *Deep*, from the nucleus vagi, at the lower part of the floor of the fourth ventricle. *Exit*:—By the jugular foramen.
14. TRIFACIAL NERVE. *Origin*:—(1) *Superficial*, from the side of the pons varolii; (2) *Deep* (sensory root), from the medulla, and upper part of cord; (motor root) from floor of fourth ventricle, and side of the aqueduct of Sylvius. *Exit*:—The ophthalmic division, through the sphenoidal fissure; the superior maxillary division, through the foramen rotundum; the inferior maxillary division, through the foramen ovale.
15. The *middle mediastinum* contains:—The heart in the pericardium, ascending aorta, lower half of superior vena cava, pulmonary artery, pulmonary veins, phrenic

nerve, termination of vena azygos major, roots of lungs, and some bronchial lymphatic glands.

16. The *subdivisions of the alimentary canal*, are:—Mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, and ileum), and large intestine (cecum, colon and rectum).

17. The sigmoid flexure is in the left inguinal region; the vermiform appendix is in the right inguinal region.

18. The ductus communis choledochus opens into the duodenum, about three or four inches below the pyloric orifice.

PHYSIOLOGY.

1. The four elements contained in all quaternary proximate principles, are: Carbon, hydrogen, nitrogen, and oxygen.

Practically, all albuminoids must be changed into peptones before absorption.

2. The intestinal glands, are: (1) Brunner's glands, found chiefly in the duodenum; (2) Lieberkuhn's glands, found throughout the small and in the large intestine; (3) the solitary glands, found throughout the small and large intestine; (4) Peyer's glands, are found throughout the small intestine, but chiefly in the ileum.

The secretion of all the glands of the small intestine (but particularly from Lieberkuhn's glands) constitutes the succus entericus; this contains the following ferments: Enterokinase, erepsin, secretin, maltase, lactase, and invertase or invertin.

5. HYPOGLOSSAL NERVE. *Origin*: (1) Superficial, from groove between the pyramidal and olivary bodies of the medulla; (2) *Deep*, from nucleus on floor of fourth ventricle. *Function*: Motor nerve of tongue.

CHEMISTRY.

1.

MERCUROUS COMPOUNDS.	MERCURIC COMPOUNDS.
(1) H_2S a black ppt., insol. in NH_4HS, HCl, or HNO_3.	ppt. at first white, then orange, then black.
(2) NH_4HS a black ppt., insol. in excess.	ppt. white to black, insol. in excess, except in presence of organic matter.
(3) KHO a dark gray ppt., insol. in excess.	yellowish-red ppt.
(4) KI a greenish ppt.	yellow to salmon to red ppt.

(From Witthaus' *Laboratory Guide.*)

2. TWO PREPARATIONS OF SODIUM—

CHEMICAL NAME.	FORMULA.	PHARMACEUTCAL NAME.
Disodic tetraborate.	$Na_2B_4O_7$.	Sodium borate, or borax.
Sodium sulphate.	Na_2SO_4.	Glauber's salt.

3. *Leucomains* are basic nitrogenous substances produced in living animals, by the decomposition of proteid matter, during normal metabolism.

Antitoxins are substances in the blood serum of an animal which will protect that animal from a specific disease, or counteract the poisonous effect of toxins.

4. *Chemical antidote to morphine*, is solution of potassium permanganate; it acts by destroying the morphine.

The *physiological antidote* is atropine; it acts by antagonizing the action of the morphine on the respiration and circulation.

5.

	NORMAL REACTION.	TO WHAT DUE.
Pancreatic juice.	Alkaline.	Sodium and potassium carbonate.
Gastric juice.	Acid.	Hydrochloric acid.

MATERIA MEDICA AND THERAPEUTICS.

2. VERATRUM VIRIDE. *Preparations*: Fluid extract of veratrum; tincture of veratrum, veratrine (with oleate and ointment of veratrine).

Physiological actions: "On the skin it causes tingling, numbness, and anesthesia, and, applied to the mucous membrane of the nose and throat, violent sneezing and coughing. Internally it produces gastro-intestinal irritation, prolonged relaxation of striped and cardiac muscle, reduction of arterial pressure, depression of respiration, convulsions from stimulation of the spinal cord, free diaphoresis, and reduction of temperature."

Therapeutical action: "As a circulatory depressant, given early, in croupous pneumonia, pleurisy, hepatitis, maniacal delirium, etc., with strong, bounding pulse and other sthenic conditions; in puerperal convulsions and the early stage of peritonitis, phlebitis and other inflammatory affections of the puerperal state; also acute rheumatism, tonsilitis, aneurysm, and wounds of the head, pericardium and peritoneum."—(Wilcox, *Materia Medica.*)

3. GELSEMIUM. *Preparations*: Fluid extract of gelsemium; tincture of gelsemium.

Physiological action: "When given internally gelsemium acts as a powerful depressant to the respiratory circulatory, and nervous systems. It acts as a depressant to the heart muscle and vagus nerves, and under its influence there is a diminution in the pulse force and blood pressure. It primarily depresses the sensory side of the spinal cord; but later, if given in large amount, depresses the motor side. The drug has no effect upon the spinal nerves, but the motor cranial nerves are paralyzed by large doses. In moderate amounts it causes the respiration to become slow and feeble, and in lethal quantities paralyzes the respiratory centers."—(*U. S. Dispensatory.*)

Therapeutic indications: Headache, migraine, asthma, whooping cough, nervous cough, spasmodic dysmenorrhea, torticollis, and other conditions depending upon localized muscular spasm.

4. OPIUM. *Official preparations*: Pulvis opii, extractum opii; pulvis ipecacuanhæ et opii, acetum opii, tinctura opii, tinctura opii camphorata, tinctura opii deodorata, tinctura ipecacuanhæ et opii, vinum opii.

Six principal alkaloids: Morphine, codeine, narcotine, thebaine, narceine and papaverine.

Official preparations of morphine: Morphine hydrochloride, acetate, and sulphate; and pulvis morphinæ compositus.

Treatment of acute poisoning: "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach; and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop, the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropin. The urine should be drawn by the catheter."—(Witthaus' *Essentials of Chemistry.*)

5. SALOL is phenyl salicylate; the salicylic ester of phenyl.

Physiological action: Antiseptic, germicidal, anodyne, and antipyretic; it combines in most respects the actions of phenol and salicylic acid.

Therapeutic uses: As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera.

PATHOLOGY.

3. *In acute yellow atrophy of the liver*: "The liver is decreased in size and becomes remarkably soft and friable. On section there is found a variegated appearance, the prevailing color being a brownish or grayish-yellow, in which are scattered bright or dark-red areas. The yellowish areas represent the degenerated and pigmented hepatic cells; the reddish areas foci of hemorrhagic infiltration or pigmentation. The process usually begins in the left lobe, but rapidly involves the entire organ. Sometimes the liver is increased in size during the initial stages, and occasionally a liver enlarged by previous disease suffers terminal acute atrophy. Microscopically the hepatic cells are found to have undergone rapid fatty degeneration or necrosis, and are filled with or replaced by yellowish pigment particles. As the process advances, the cells are completely destroyed. In the red areas referred to, infiltration with blood-cells and hematogenous pigmentation are observed."—(Stengel's *Pathology.*)

4. (*a*) In *productive inflammation*, the proliferative changes are in excess of the exudation and degeneration.

(*b*) *Suppurative inflammation* is a special form of inflammation, in which the exudate is unusually prolific in cells, and in which pus is found. The cause of suppuration is the invasion of the tissues by pus producing bacteria, when the said tissues are in a state of lowered vitality or are not capable of withstanding and disposing of the bacteria and their products.

5. In *fatty infiltration* the tissues contain fat brought from without; there is no change in the cell protoplasm, and such damage as the tissue undergoes is due to the mechanical pressure caused by the fat.

In *fatty degeneration* the cell protoplasm undergoes change; the fat is in the cells, and not between them

OBSTETRICS.

2. The *symptoms of threatened eclampsia* are: Headache; tinnitus aurium; dizziness; pain over stomach; digestive, visual and nervous disturbances; general debility; insomnia, vomiting and vertigo.

3. The *causes of antepartum hemorrhage* are: Placenta prævia premature separation of the placenta; apoplexy of the decidua or placenta; rupture of varicose veins; abortion (threatened, or inevitable, or incomplete), and ectopic gestation.

PEDIATRICS.

1. PERTUSSIS. *Etiology*: It is most likely due to an organism, not yet identified; it is infectious and contagious; occurs in epidemics; and as a rule only occurs once in the same person.

Complications: Bronchitis, emphysema, pneumonia, collapse of lung, pleurisy, convulsions, hemorrhages, vomiting, diarrhea, pericarditis, and endocarditis.

Duration: Uncertain, but quite long. It is not safe for a child to return to school in less than five or six weeks from the beginning of the attack, and not even then unless the "whoop" and spasmodic cough have ceased for at least two weeks.

2. The *treatment of acute adenitis* consists in: Prompt and frequent application of ice-bags; an ointment of ichthyol and zinc oxide may be used; the source of the infection must be treated, hence adenoids, carious teeth, enlarged tonsils, grippe, diphtheria, tonsillitis, scarlet fever or other exanthemata must be properly treated if present. Free incision and drainage are indicated if pus is present.

3. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the new-born.

It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is: (1) *Prophylactic*: Whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent solution of nitrate of silver, immediately after birth. (2) *Remedial*: Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent solution of nitrate silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

4. SCABIES. *Symptoms*: The Itch.

Treatment: This consists in a protracted bath with soap and hot water, followed by the application of sulphur ointment (℥i to ℥i) or other parasiticide every night for one week. In the meantime, the bed linen and underclothing should be sterilized by heat. At the end of a week another bath should be taken and some sedative ointment or lotion should be prescribed. Sulphur may be substituted by beta-naphthol, balsam of Peru, styrax, tar, staphisagria, etc. (Gould's and Pyle's *Cyclopedia of Medicine and Surgery*.)

GYNECOLOGY.

2. In *Ovaritis*: There is generally a history of pelvic inflammation, the pain is more or less constant, and on examination the ovary is found to be enlarged and tender.

In *Ovaralgia*: There is no history of pelvic inflammation, the pain is not constant, and on examination the ovary is found to be normal.

4. Yes; ventrofixation of the uterus is justifiable. Circumstances justifying it are: Extreme retroflexion, and prolapse of the uterus.

5. The *menopause* is the period when menstruation ceases.

The following (from Dudley's Gynecology) will explain why the menopause is a critical period in a woman's life:

The symptoms of the menopause are referable to two stages: a stage of menstrual irregularity preceding the cessation of the menses, and a post-cessation stage of variable systemic disturbances. In normal or nearly normal cases the irregularities are not excessive; the systemic disturbances are slight. There is a period of unstable equilibrium. The woman may at times be unusually capricious and emotional; yet she passes through this physiological crisis with only a few minor disturbances. She may have the characteristic vasomotor flushes, perspiration, vertigo, somnolence, numbness, and faintness. The menstrual function ceases as it began, with marked symptoms referable to the nervous system. Irritability, apprehensiveness, hysteria, melancholia, and other psychic disturbances are common in the abnormal cases, and may be exaggerated. The menstrual deviations vary in wide limits. The flow may gradually decrease and come at lengthening intervals until it altogether ceases; it may occur at short intervals or become continuous; it may become so excessive as almost to amount to dangerous hemorrhage; or life may be jeopardized by a slow, continuous drain. There is an increased tendency to malignant disease of the uterus and breasts during this period. The excessive fear of this may prey injuriously on the mind of the woman.

SURGERY.

1. An *abscess* is a circumscribed collection of pus in a cavity of new formation.

An *aneurysm* is a pulsating sac containing blood, and communicating with the lumen of an artery.

An aneurysm may be confounded with: Tumors, cysts or abscesses lying over or in close proximity to the course of the artery; vessels which are pulsating abnormally; vascular tumors such as goiter or sarcoma.

2. The following table (from Eisendrath's *Surgical Diagnosis*) gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic, high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

3. *Peritonitis* is inflammation of the peritoneum.

4. *Ways in which the peritoneum may be invaded by bacteria*: By penetrating wounds; from injury, perforation or ulcer of the stomach or intestines; from gonorrhea, through the fallopian tubes; from septic infection of the female genital tract.

5. *Contraindications to use of nitrous oxide*: Vascular degeneration; advanced heart disease; conditions in which muscular relaxation is required.

The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics*: "Ether should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

6. *Dislocation* is a displacement (partial or complete) of the articular end of a bone.

Fracture is a sudden forcible solution of the continuity of a bone.

7.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

8. *Colles' fracture* is a fracture of the lower end of the radius; it is generally transverse, and is usually within an inch or an inch and a half of the articular surface. There is a characteristic deformity caused by the lower fragment, and the carpus forming a prominence on the dorsal surface; at the same time there is a projection on the palmar surface just above the wrist, caused by the upper fragment. The hand is abducted and pronated, and the styloid process of the ulna becomes very prominent. It is generally caused by a fall on the outstretched palm.

10. *Hemorrhage* is loss of blood from some part of the arterio-venous system.

11. *To arrest epistaxis*: (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

12. LIGATION OF THE SUBCLAVIAN ARTERY IN ITS THIRD PORTION: "*Position.* Patient supine; shoulders raised; head thrown back and to the opposite side; operated shoulder depressed by arm drawn downward and placed under the back (to open out the posterior cervical triangle). Surgeon in front of shoulder. *Incision.*—With the skin of the posterior cervical triangle drawn down over the clavicle by the left hand, an incision about three inches is made transversely over the clavicle down to the bone, from the posterior border of the sternomastoid to the anterior border of the trapezius, and with its center about one inch internal to the center of the superior border of the clavicle. *Operation.*—(1) This incision will divide the skin, fascia, platysma, some supraclavicular nerves, and maybe a connecting vein between the cephalic and internal jugular—but will avoid the external jugular, which passes through the deep fascia above the clavicle. The incision will lie about half inch above the clavicle when the tension upon the skin is relaxed. (2) The margins of the sternomastoid and trapezius will be exposed, and, if more room be needed, may be divided along the clavicle as far as necessary. (3) The deep cervical fascia is next incised, the external jugular vein being carefully exposed and retracted, or divided between double ligatures. Tributary veins of the external jugular are to be similarly treated, especially the transversalis colli and suprascapular. (4) Generally the transversalis colli artery lies transversely above the incision, and the suprascapular transversely below it, under the clavicle and out of the way; but one or both may be present in the field, and are to be carefully preserved for collateral circulation. Retract the posterior belly of the omohyoid upward if in the way. Identify the outer margin of the scalenus anticus (just under the outer margin of the sternomastoid) as a guide to the artery, and follow its outer border downward until the finger reaches the tubercle on the upper border of the first rib, which lies between the subclavian vein in front and the subclavian artery behind—when the artery will be recognized and may be traced upward. (5) Expose the lowest cord of the brachial plexus—for the purpose of henceforth avoiding it (as it has been mistaken and ligated for the artery). The subclavian vein will lie anteriorly and inferiorly to the artery. (6) Open the sheath—clear the artery—and pass the needle from the brachial plexus, guarding the subclavian vein and the pleura." (From Bickham's *Operative Surgery.*)

13. The arteries which require ligating in amputation at middle third of leg, are: Anterior tibial, posterior tibial, and peroneal.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	W. H. Sanders, Montgomery	Montgomery July 13
Arizona*	Ancil Martin, Phoenix	Phoenix July 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock July 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver July 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven July 13
Delaware	J. H. Wilson, Dover	Dover Dec. 14
Dist. of Col'bia	Geo. C. Ober, Washington	Washington July 13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise Oct. —
Illinois	J. A. Egan, Springfield	Chicago July 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis July 13
Iowa	Louis A. Thomas, Des Moines	Des Moines Sept. —
Kansas	D. P. Cook, Clay Center	Kansas City Oct. 12
Kentucky	J. N. McCormick, Bowling Green	Louisville July 6
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta Nov. —
Maryland	J. McP. Scott, Hagerstown	Baltimore Dec. 14
Massachusetts*	E. B. Harvey, State House, Boston	Boston July 13
Michigan	D. D. Harison, 205 Whitney Building, Detroit	Lansing Oct. 12
Minnesota	W. S. Fullerton, St. Paul	St. Paul Oct. 5
Mississippi	S. H. McLean, Jackson	Jackson Oct. 12
Missouri	J. A. B. Adcock, Warrensburg	Kansas City Sept. 20
Montana*	Wm. C. Riddell, Helena	Helena Oct. 5
Nebraska	E. J. C. Sward, Oakland	Lincoln Aug. 3
Nevada	S. L. Lee, Carson City	Carson City Nov. 1
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord
New Jersey	J. W. Bennett, Long Branch	Trenton Oct. 19
New Mexico	J. A. Massie, Santa Fe	Santa Fe July 12
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York Albany Syracuse Buffalo Asheville Sept. 21
N. Carolina	B. K. Hays, Oxford	
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks July
Ohio	Geo. H. Matson, Columbus	Columbus Dec. 14
Oklahoma*	F. P. Davis, Enid	Guthrie July 13
Oregon*	B. E. Miller, Portland	Portland July
Pennsylvania*	N. C. Schaeffer, Harrisburg	Philadelphia Dec. 14 Pittsburg
Rhode Island*	G. T. Swarts, Providence	Providence Oct. 7
S. Carolina	H. H. Wyman, Aiken	Columbia June —
S. Dakota*	H. E. McNutt, Aberdeen	Watertown July 14
Tennessee	C. A. Abernathy, Pulaski	Memphis Nashville May — Knoxville
Texas	C. B. Foscue, Waco	Cleburne
Utah	R. W. Fisher, Salt Lake City	Salt Lake City July 5
Vermont	W. Scott Nay, Underhill	Burlington July 13
Virginia	R. S. Martin Stuart	Richmond Dec. 14
Washington*	K. Turner, Seattle	Seattle July
W. Virginia	H. A. Barbee, Point Pleasant	Charleston July 13
Wisconsin	J. V. Stevens, Jefferson	Madison July 13
Wyoming	S. B. Miller, Laramie	Laramie

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Magnesium Sulphate in Tetanus.—McPhedron reports a case of tetanus in a boy of thirteen. The incubation period was seven days. For ten days chloral and morphine were given, with no improvement. On the tenth day antitetanic serum was used. The boy grew worse. On the twelfth day 2 c.c. of a 25 per cent solution of magnesium sulphate were injected intra-spinally and 3 c.c. more the next morning. There were no further convulsions, and the boy improved steadily and recovered. McPhedron says that to date eleven cases of tetanus treated by this method of Meltzer have been reported, with six recoveries.—*The Canadian Journal of Medicine and Surgery.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the weeks ending June 19 and 26, 1909:

	June 19		June 26	
	Cases	Deaths	Cases	Deaths

LEPROSY.

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

THE great popular interest and excitement which has been aroused by the long imprisonment of a suspected leper, in Washington, D. C., warrants a medical consideration of leprosy in a manner which may perhaps, in some way, tend to a greater enlightenment on the subject; this refers not only to the public at large, but also to those in the profession who possibly may not yet have perfectly clear ideas on the subject.

Ever since Biblical times the leper has been considered as "unclean," and in certain localities, even up to the present time, the afflicted person cries out, or by a bell or other means indicates his presence, that he may be shunned, from the supposed fear of infecting others. The great dread of the disease leprosy has undoubtedly been furthered by many writers of fiction, and such books as "Ben Hur" have had great influence; on the other hand, there has been very little said or done to check or lessen the popular prejudice in this direction, which has been too often shared by physicians, who, not having devoted special attention to the matter, accept thoughtlessly the general verdict.

Undoubtedly this popular prejudice against leprosy has also been fostered by the fact that in many countries it has seemed advisable to provide special hospitals or asylums for lepers, where they can be better cared for than in their poor, crowded homes, and also by means of which the slight possibility of the spread of the disease, by methods thus far unknown, may be minimized.

So that to-day it may safely be said that the word "leprosy" strikes more terror into the heart of its victim, or suspected victim, and also into the mind of the average layman, or even physician, than that of almost any other disease known; and yet, to those who are really well informed, it bears no comparison to either cancer or tuberculosis in the mental distress which it should cause in those afflicted, while syphilis and many other diseases should inspire far more dread of contagion. Few realize that, in this climate at least, leprosy is really a harmless affection to those who may come in contact with it. A good many years ago the Leprosy Committee of the Royal College of Physicians of London wrote as follows*: "The all but unanimous conviction of the most experienced observers in different parts of the world is quite opposed to the belief that leprosy is contagious or communicable by proximity or contact with the disease." And recently, in connection with the Early case, Dr. William H. Welch, of John Hopkins Hospital, remarked: "Leprosy is practically the least contagious of all the infectious diseases."

It may be interesting to briefly refer again to the Biblical use of the word leprosy, whence has come so much of the inspiration toward the senseless fear which still pervades so many.

It may seem a little startling, but, after careful, prolonged and repeated study of Leviticus, chap. 13 and 14, and of all the other references to leprosy in the Bible, I am convinced that what we now know by that name was not intended or included in the descriptions given; I am supported in this view by one of the brightest and most learned of the professors in the Union Theological Seminary. So that it is improper to apply the term, "the leprosy of the Bible" to the disease under discussion, lepra, or elephantiasis Græcorum, as studied so thoroughly in Norway and observed abundantly in the East, and more or less over various portions of the earth.

It would lead us too far away from our main subject if we attempted to analyze here all the material found in the Bible concerning what is there called "a leprosy," but brief mention of some points may not be without interest.

It is to be remembered that the Levitical law was given at Sinai, or soon after, when there was an enormous, untrained horde of Israelites, recently escaped from bondage, who were being welded into a nation, during forty years of a roving, nomad life. In order rightly to shape this people the great lawgiver Moses, by divine direction, formulated many laws and rules, in regard to health as well as in regard to moral and religious matters, which formed the basis for the national life of the Jews for many centuries, and are operative in a measure even to the present day.

Now among the many ordinances relating to health it became necessary to treat of diseases appearing on the skin, some of which are contagious and which, if neglected, would readily spread among those living together in tents, unless some sanitary precautions were taken. We must remember, however, that there were no books and no medical science in those days, but that the priests were about the only ones who possessed knowledge of any kind. Consequently we find in Leviticus just about what we would expect, a layman (in medicine) Moses, writing for lay priests, and consequently it is by no means a scientific discussion of the subject of leprosy.

It is, therefore, no wonder that the description of the various conditions found on the skin should be more or less confused, so that only by the most careful study can one make out what is intended. Several who have investigated the matter state that undoubtedly a number of different diseases appearing on the skin are included in the Biblical accounts, and one can discover indistinct references sufficient to identify some of them; thus, writers have found

*Report on Leprosy, by the Royal College of Physicians, London, 1867.

allusion to syphilis, favus, ringworm, pinta, scabies, psoriasis, eczema, morphœa, leucoderma, and perhaps other affections on the skin, but, as intimated before, no one well acquainted with true leprosy, as recognized to-day, would be able to find any description at all fitting to any of its symptoms in the Bible. The cry of "unclean, unclean," and the separation of those afflicted, without the camp, related therefore to various eruptions on the skin and not at all to present-day leprosy, and affords not the slightest reason for such action to-day.

This study of the use of the word leprosy in the Bible is a most interesting one, but cannot here be pursued much further for want of space. It may be interesting to note that in several places the expression is used, "a leper white as snow." Now we know that neither the tubercular nor the macular leprosy ever presents a white diseased surface, and these instances probably related to psoriasis, as in the case of Moses' hand, Miriam, and Gehazi; also in many places the Bible speaks of the skin turning white with white hair on it, referring to leucoderma, etc. It is to be remembered that not long ago the word lepra, now exclusively applied to leprosy, or elephantiasis Græcorum, was a common designation for psoriasis, used thus by Mr. Erasmus Wilson of London, and also as the title of quite a large book on psoriasis, by George Gaskoin; while the word "lepra" is used in the Greek New Testament to indicate the leprosy of the Bible, and this word lepra means scales. Finally, the word *zara'ath*, translated leprosy in the Old Testament, signifies a smiting or stroke, and in the German of the middle ages the same word was translated *aussasaig*, indicating an outcast, or one unfit to live with others.

In regard to the manner in which leprosy, as we now know it, is considered by those who come often in contact with it, it may be mentioned that in all the clinics in Europe, and in this country, as far as I know, patients thus afflicted mingle freely with others and are lectured upon and handled just as any other patients, and never has there been known any instance of harm therefrom. They are also constantly admitted to the beds of hospitals, without any thought of danger. In 1868, over forty years ago, before the days of antisepsis, when the writer was interne in the old New York Hospital, a most distressing case of tubercular anesthetic leprosy, with much ulceration and mutilation, was for a long time in the medical wards, and was then transferred to the surgical service, where a portion of the foot was amputated without an anesthetic, there being no pain. The proof that none of these cases proved contagious is found in the fact that among the many patients with unquestioned leprosy who are brought before the New York Dermatological and other societies, there are very seldom any instances of leprosy found which have developed *de novo* without having been in countries where the disease is endemic.

The testimony which could be given in regard to the non-contagiousness of leprosy is very great, and from all parts of the world. Perhaps the most striking is that furnished by Father Clement, whose death was very recently reported from Honolulu. Father Clement went from France in 1863, with Father Damien, to devote his life work among the lepers in the settlement on Molokai; he had thus been there for forty-six years, in constant contact with lepers, and finally died of other cause, without having contracted the disease.

Similar testimony is furnished from innumerable leper hospitals and asylums, many dating back fifty years and more, where scores and hundreds of nurses have cared for patients with leprosy, in all forms and stages of the disease, without becoming affected, and that also even in districts where leprosy is endemic. Dr. Beaven Rake, for many years medical superintendent of the leper hospital in Trinidad, wrote a while ago as follows: "The Trinidad Leper Asylum has been nursed by Dominican nuns since 1868. These sisters are in daily contact with the patients, washing their sores, applying poultices and bandaging their crippled limbs; yet no sister, nor any other of the attendants has yet developed the disease." The same testimony is borne by Dr. Van Allen in regard to the leper hospital in Madras, India, where there were one hundred and fifty lepers, none of the dressers who freely handle even ulcerated surfaces have contracted the disease. In very few places is segregation compulsory, and even in Norway lepers are allowed to live in their own houses if they desire.

If leprosy, therefore, is not contracted by contagion or contact, in what way is the disease acquired? Unfortunately this question has not yet been answered definitely, for neither race, climate, soil, nor hygiene can be charged, so universally spread is the disease; heredity has been excluded by many observers. Some argued that the bacillus finds entrance through the air passages, and it has been thought that the primary lesion occurred in the nose; but this has never been satisfactorily demonstrated.

There is one more great means by which the organism may enter the system, and that is through food or drink. For a great many years various observers have claimed, with more or less force, that there was the greatest probability that the disease was conveyed through fish, in some way or other. Mr. Jonathan Hutchinson of London, well known as a minute observer and careful thinker, has of late years been the chief advocate of this mode of the diffusion of the disease; and in the light of modern knowledge regarding the conveyance of various diseases by means of lower animal life, the theory would seem to have fresh scientific support. Of course, this would not relate to all fish, but to certain kinds, and even these might not give the disease unless they had in some way acquired the contagious principle, even as the mosquito may be harmless except when infested with the germ of malaria or yellow fever. I know that Mr. Hutchinson's continued and warm advocacy of the fish theory has been subjected to much ridicule, and is not generally accepted; but to my mind it offers the most satisfactory solution of the problem, and better accounts than any other, both for the great prevalence of the disease in certain localities, and also for sporadic cases of leprosy in those who have never been in leprous districts or who have never in any way been exposed with those thus affected. Mr. Hutchinson's arguments in favor of the fish hypothesis are so clear and strong that I must give some of them, condensed:

"No other article of food can be mentioned which is in use in all leprosy districts. Most of the places where leprosy is largely prevalent are on the sea coast, and it is especially common on islands. Wherever a community is found which subsists largely on fish, there leprosy is present. Almost all the large fish-curing locations are the homes of leprosy, and it is often met with also in the countries to which their products are most freely exported. It is not necessary, of course, that a large quantity of fish

be eaten, for the smallest portion, if it contains the germ can introduce the disease. Thorough cooking of fresh fish probably destroys its power of communicating leprosy, if it chance to be infected, but it is known that fish are often eaten raw, or improperly cooked, and also that very large quantities of dried fish are consumed throughout the world, often as a condiment with vegetable food, and even by those belonging to religious castes who will not take animal life."

An illustration of a possible mode of conveyance is found in Russian *caviare*, made from the roe of several varieties of fish, which is always eaten uncooked. If the raw oyster can be the means of communicating typhoid fever, what is there unreasonable in believing that fish, under certain circumstances, can introduce leprosy? Not long ago Mr. Hutchinson restudied the subject, and made an extensive trip to countries where leprosy is endemic, and was more than ever convinced of the truth of the fish hypothesis. There is certainly enough reasonableness in the theory to warrant careful scientific inquiry along modern lines of bacterial research.

531 Madison Avenue

DIAGNOSIS AND LOCALIZATION OF APPENDICAL ABSCESSES.*

By CASSIUS C. ROGERS, A.M., M.D.,

CHICAGO,

PROFESSOR AND HEAD OF THE DEPARTMENT OF SURGERY IN THE CHICAGO COLLEGE OF MEDICINE AND SURGERY; SURGEON TO FRANCES WILLARD HOSPITAL.

Of the many diseases of the abdominal viscera that are brought to the general surgeon's attention, none are more numerous than appendicitis and its complications; the symptoms of typical appendicitis are so marked and readily recognized that a wrong diagnosis is seldom and should never be made. Quite the contrary can be said of the obscure atypical forms.

It will be the endeavor of the writer to review his experience, and although nothing new may be presented, it is hoped that it may enable some one to make an earlier diagnosis in obscure appendicitis than is often done so that the surgeon can achieve greater success after operation, thereby lowering the mortality following the operation for appendicitis. I will quote no authority, although I may repeat what has been written many times before. Therefore, I claim nothing original for this paper, simply appendicitis as I have found it in the home, the hospital, and the operating-room.

The appendix is a part of the alimentary tract, its base attached to and its lumen communicating with the cecum, its apex occluded and unattached. Its normal length is from two to three and one-half inches, although it may be wanting or merely a rudimentary stump not more than one-half inch in length, or it may be abnormally long—from eight to nine inches. The lumen is small, not exceeding, as a rule, one to two-tenths of an inch. The location of the appendix depends upon that of the cecum, as it is attached to the distal end of the cecum and moves with it, and wherever it is possible for the cecum to wander in the abdominal cavity, it takes the appendix with it.

Development of the Appendix (Fig. 1).—The alimentary canal at fourth week. (Bonnet.) The intestinal canal grows in length much more rapidly than does the embryonic body. Therefore, the tube becomes bent and thrown into convolutions.

During the sixth week the alimentary canal has not only increased in length but certain changes in position of the organs have taken place. A U-shaped tube has appeared and attached itself to the ventral wall, a point in the lower limb of the U-shaped tube now increases rapidly in size, this forms the cecum.

At the end of the sixth week the cecum and colon lift themselves forward and assume a position ventral to the small intestines, the cecum occupying a position to the right hypochondrium (Fig. 2) region and the colon passing transversely across the abdomen ventral to the duodenum. In the third month the appendix has already formed. When the cecum was first formed no appendix was present, but soon

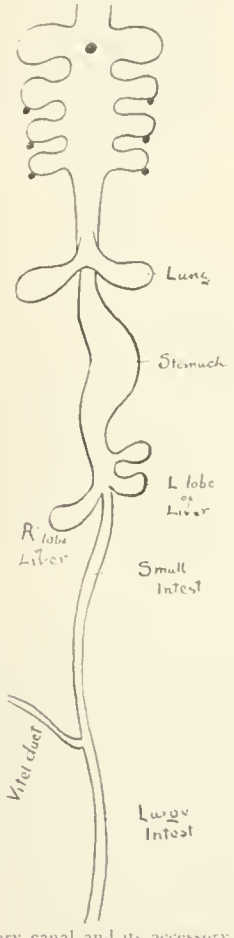

Fig. 1.—The alimentary canal and its accessory organs, in the fourth week (after Bonnet).

the cecum increases in size much faster than the distal portion and a slender tube is the result. The cecum now begins to move downward so that in the seventh month it is below the right kidney (Fig. 3), while in the eighth month it passes the crest of the ilium (Fig. 4).

Normally the base of the appendix is located at a point about one-third the distance from the anterior superior spinous process of the ilium to the umbilicus. If the cecum and descending colon are abnormally long or movable it may extend into the true pelvis, and the appendix, therefore, be located, in the female, back of the uterus and even into the cul-de-sac (Case I, Fig. 5), and in the male, back of the bladder (Case II). It may be located in a right inguinal hernia and an abscess be located in the scrotum (Case III, Fig. 6), rarely in a left inguinal hernia. It may be found in a femoral hernia. The

*Read before the Chicago Medical Society.

cecum may appear abnormally short, almost absent, with a short ascending colon, with the appendix lying near the hepatic flexure in close apposition to the liver. An abscess will be sub-phrenic or subhepatic (Case IV, Fig. 7). The appendix may lie

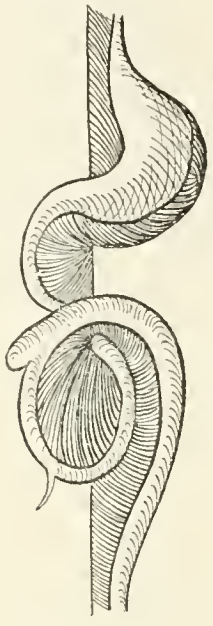

Fig. 2.—The cecum in the region of the liver, at the third month (Heisler).

transversely across the abdominal cavity, its body and apex adherent to the sigmoid flexure, an abscess located on the left side (Case V, Fig. 8). The appendix may be wholly intraperitoneal. It may be attached by a short mesoappendix, and the direction of the appendix in relation to the cecum may be first downward and lying in an S-shaped position (Fig. 9), normal position; second, the mesoappendix may be long or wanting so that the direction of the appendix is downward, its body crossing the illiac vessels and the tip extending into the pelvis. It may be turned so that its apex is directed upward toward the liver. This may be (1) anterocecal, lying in front of and between the cecum and the ascending colon and the anterior abdominal wall. An abscess will be anterior to the ascending colon (Case VI); (2) retrocecal, lying back of and between the ascending colon and the posterior abdominal wall, the appendix touching or lying back of the liver. An abscess will cause a sub-phrenic abscess (Fig. 10). It may be turned along the cecum until it reaches the iliocecal valve and extend along the ilium the remainder of its course (Case VII, Fig. 11). An abscess will cause intestinal obstruction.

In any of the above positions it may be perfectly free from adhesions, normal in all respects, and cause absolutely no difficulty or symptoms. It may become inflamed and bound down by adhesions in any of these positions, when it becomes a factor of grave importance.

If the tip is directed toward and extending into the pelvis, an acute suppurative condition will simulate a pelvic abscess and be complicated with all the findings of a true pelvic abscess. Symptoms of cystitis are almost invariably present in males, and of pyosalpinx in the female (Cases I and II, respectively), as well as painful defication in both.

The appendix may extend along the cord and be adherent to it within the inguinal canal (Case IX). In the non-descendent variety of appendicitis where there is a descended cecum, the tip of the appendix is directed upward and forward, or upward and backward. The symptoms may be very severe, or, on the other hand, may be almost absent, and the condition be of equal gravity. In the variety in which the symptoms are severe they are usually accompanied or followed by an acute suppurative condition; while the symptoms that appear to be less severe are usually followed by a gangrenous condition. Either may be complicated by symptoms simulating intestinal obstruction, empyema of the gall-bladder, pancreatitis, pyloric obstruction, subphrenic abscess, ulceration or gangrene or the hepatic flexure of the colon, pleurisy and pneumonia.

Nature has a tendency to wall off an inflamed appendix from the abdominal cavity and the omentum is frequently found wrapped entirely around it, forming a tumor with the appendix in the center of the mass. If an abscess forms after the omental tumor is formed there is little danger of diffuse peritonitis.

The complications of non-descendent intraperitoneal appendicitis are emphema of the gall-bladder, ulceration and gangrene of the hepatic flexure of the colon, inflammation of the duodenum and pancreas (Case X, Fig. 11), subphrenic abscess (Case IV, Fig. 7). Any of these may be complicated with localized or diffuse peritonitis.

The appendix may be wholly or partially extraperitoneal: (1) The base may be intraperitoneal, its direction backward and upward so that the body is wholly extraperitoneal and the tip appearing intraperitoneal so that a rupture of the appendix near the base or the tip will cause intraperitoneal infection. Rupture of the base will form an abscess in the right inguinal region. This may extend and localize in the left inguinal region, the attachment of the

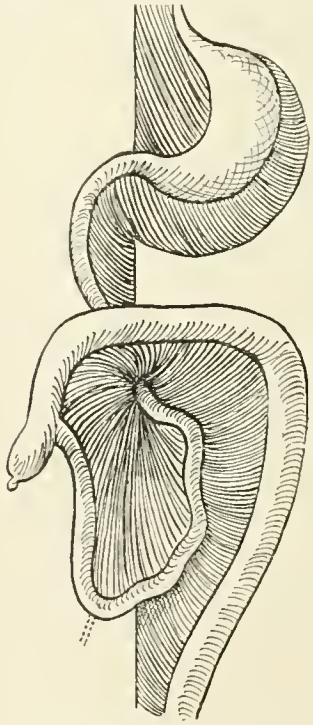

Fig. 3.—The cecum at the lower pole of the kidney, at the seventh month (Heisler).

mesentery of the small intestines directing the pus to the left inguinal region. Rupture of the tip will cause a subphrenic abscess (Fig. 13), while rupture of the body will cause an extraperitoneal abscess. (2) The base and body may be extraperitoneal, the

tip intraperitoneal, in this case a rupture of the base and body causing an extraperitoneal infection and of the tip an intraperitoneal infection (Fig. 14). (3) The base may be intraperitoneal and one side of the appendix covered its entire length with

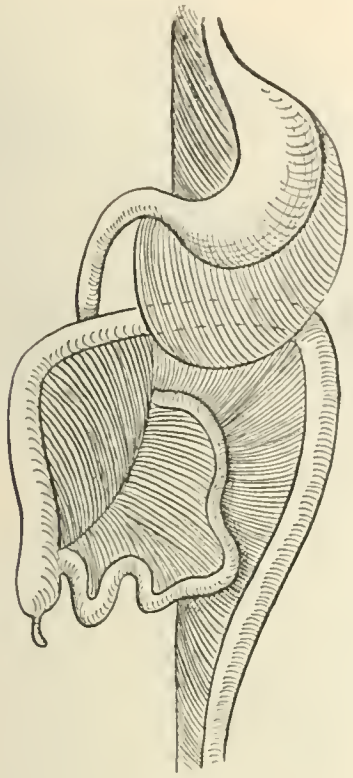

Fig. 4.—The cecum below the crest of the ilium, at the eighth month (Heisler).

peritoneum, while the other side is extraperitoneal. In this instance a rupture of the side covered with peritoneum will cause an intraperitoneal infection, while a rupture of the side devoid of peritoneum will cause an extraperitoneal abscess (Fig. 15). An appendix located close to and parallel with the ureter may cause inflammation of the ureter and symptoms of renal colic as well as pyelitis (Case X, Fig. 16). (4) In other cases the cecum may be well attached and high up so that to find the base of the appendix the surgeon must go through the peritoneum, the appendix being wholly extraperitoneal and a rupture along any of its course will cause an extraperitoneal abscess (Case XI, Fig. 17). It is in this variety of cases that the amateur surgeon operates on what appears to be a typical case of appendicitis, seeks for the appendix, fails to find it, closes the abdomen thinking that the patient has no appendix and that the diagnosis is wrong; but discovers a few days later that the patient has, what appears to be a paranephritic abscess, drains, and finds a colon bacillus infection and an appendix extraperitoneal.

The appendix may become attached to the abdominal wall, the lumen patulous forming a fecal fistula (Case XII, Fig. 18).

Case I. (Fig. 5).—Appendix lying back of the uterus, apex in the cul-de-sac, the condition simulating pyosalpinx. Mrs. S., aged 43. Entered the Willard Hospital May 2, 1907. Family history negative with the exception that patient stated she had pneumonia in January, but recovered completely. Ten days previous to entering the hospital she was again seized by pains in the left pleural region; also, diffuse abdominal pains, at which time she was seen by Dr. Hood, who made a diagnosis of pleurisy. She improved until the day before entering the hospital, when she was again seized by diffuse abdominal pain, nausea, and vomiting.

Blood analysis: Hemoglobin, 80 per cent.; 57,530 leucocytes, over 97 per cent. of which were polymorphonuclears.

I saw her with Dr. Hood, and diagnosis of pelvic abscess was confirmed. She was taken to the operating-room at 9.10 A.M. The cul-de-sac was opened and a large appendical abscess was drained through the vagina. She left the operating room at 9.45. May 10 the temperature suddely rose to 103, respirations rapid and shallow. On aspirating the left pleural cavity pus was found. May 11 she was taken to the operating-room at 10.30 A.M. and again anesthetized, chloroform being used. The eighth rib was resected and rubber-tube drainage established. She left the operating-room at 10.50. Leucocytes at this time were 36,400, polymorphonuclears 90 per cent. May 16 the temperature was 100°, pulse, 110; respiration, 40; 26,200 leucocytes; polymorphonuclears, 82 per cent. At the request of the patient and her husband, she was removed from the hospital to her home, where she died two weeks later from pneumonia.

Case II.—Appendix lying back of the bladder; inflammation simulating cystitis. Mr. C. The patient was brought to the West Side Hospital after an illness of one week. He first complained of painful and frequent urination, when a diagnosis of cystitis was made and the patient was placed on the appropriate treatment. On the third day the patient complained of abdominal pain which was accompanied by nausea and vomiting, also constipation. A brisk cathartic was administered, the patient complaining of excruciating pain on defecation. He steadily grew worse, and when I saw

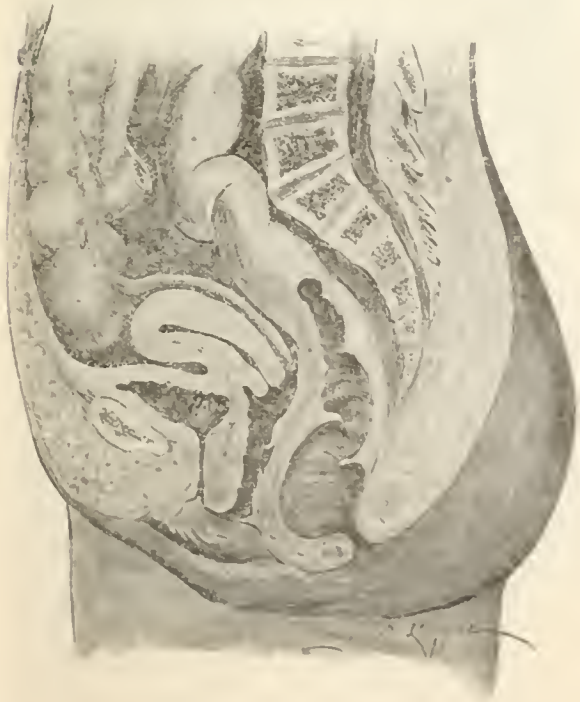

Fig. 5.—Case I: Appendix lying back of the uterus, suppuration resulting in an abscess in Douglas' cul-de-sac.

him he was suffering from diffuse extending peritonitis. A diagnosis of peritonitis following appendicitis was made. Upon incision in the right inguinal region the abdominal cavity was found to be free from adhesions; the appendix, located well

back of the bladder, was removed, the condition being a ruptured acute suppurative appendicitis which first formed an abscess back of the bladder followed by a general peritonitis. Drainage was established by passing a rubber tube well into the pelvis, the patient placed in the Fowler position. Normal saline solution was given per rectum, but the patient died two days later as result of the diffuse peritonitis. This was a case of prolapsed cecum with the appendix lying in the pelvis back of the bladder, an abscess had formed which irritated the bladder, giving rise to symptoms of cystitis, and a mistaken diagnosis running over a period of seven days proved fatal.

Case III (Fig. 6).—Appendix located in the lower part of the scrotum in a right inguinal hernia. Mr. M., aged 51. Entered the Frances Willard Hospital Oct. 16, 1906, and was operated for right inguinal hernia. The hernial opening was

Fig. 6.—Case III: Appendix in the lower part of the sac of a central hernia, suppuration resulting in an abscess of the scrotum.

very large, the scrotum the size of a cocanut. Incision was made for typical Baccini operation. When the sac was opened it was found to contain the cecum, the appendix in the lower portion of the sac. The sac was emptied of its contents, the appendix removed, and the wound closed by the Baccini method. Patient made an uneventful recovery and left the hospital at the end of the third week.

Case IV. (Fig. 7)—Appendix directed upward and backward, the body adherent to the gall-bladder and the tip to the liver. Mr. S., aged 23. Dental student. Taken ill Feb. 23, 1907, with excruciating pains in the right hypochondriac region. physician was called and diagnosis of hepatic colic was made, and he was sent to the hospital where a like diagnosis was made. He soon became jaundiced, remained in the hospital for two days, when he was removed to the Frances Willard Hospital, Feb. 25, at 2.30 P.M., where I first saw him. At this time he was suffering with diffuse abdominal pain, was jaundiced, had marked rigidity of the abdominal wall; temperature, 103; blood count, leucocytes,

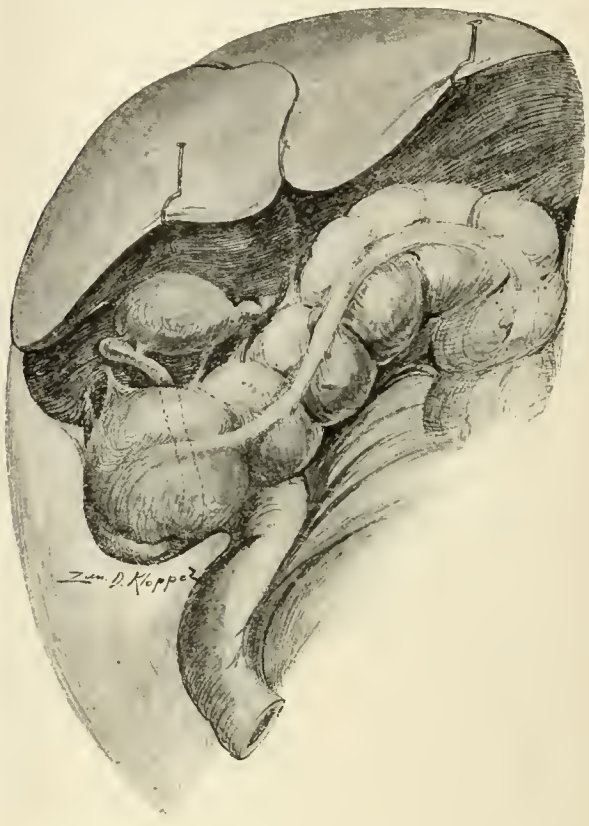

Fig. 7.—Case IV: Non-descended appendix, tip adherent to the gall-bladder, suppuration resulting in empyema of the gall-bladder.

11,000; polymorphonuclears, 86 per cent. Diagnosis of appendicitis was made. He was immediately taken to the operating-room, chloroform administered, and an incision made along the linea semilunaris from the margin of the ribs to opposite the umbilicus. The ascending colon was markedly inflamed and areas of gangrene were found. The ascending colon was followed downward until the cecum was reached, when the base of the appendix

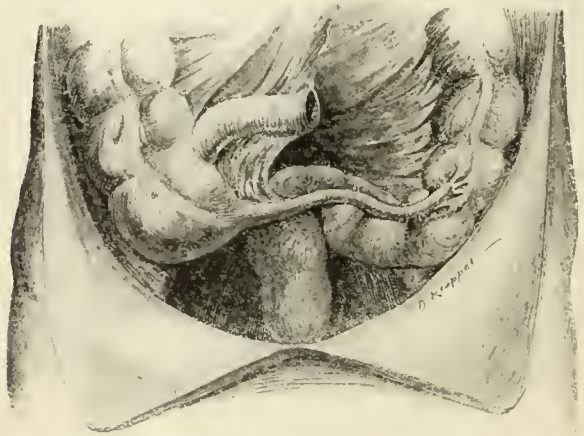

Fig. 8.—Case V: Appendix lying transversely, tip attached to the sigmoid flexure; suppuration resulted in an abscess in the left inguinal region as well as ulceration of the sigmoid.

was found to be gangrenous, and it was removed. Stripping it from between the ascending colon and the posterior abdominal wall, the tip was found adherent to the gall-bladder and the liver. The ap-

pendix was removed, and the field drained by strips of iodoform gauze. The patient made a slow but steady recovery and left the hospital at the end of the fifth week, and has had no further trouble.

Case V. (Fig. 8)—Chronic appendicitis, the appendix attached to the sigmoid flexure and the pain located in the left inguinal region. Mrs. N., Marshalltown, Ia. Entered the West Side Hospital complaining of pain in the left inguinal region, stating she had had attacks of pain lasting from two days to two weeks duration extending over a period of ten years. The pain sometimes would disappear and not recur for months, then it might occur in a very short time. Vaginal examination was negative. As she had complained of pain for so many years and had continually doctored during this period, an exploratory laparotomy was advised. The appendix was found pointing toward the left inguinal region and attached to the sigmoid flexure for at least three-quarters of its length. The adhesions were old and firm and it was with some difficulty that the appendix was loosened so that it could

Fig. 9.—Normal appendix.

be removed. Since the operation the patient has entirely recovered, and now, over five years, has not had a single recurrence of pain.

Case VI.—Appendix lying anterocecal, the tip directed upward. Mr. C., aged 39. Entered the Frances Willard Hospital Dec. 7, 1906; temperature, 101.4; pulse, 100; respirations, 24. Said that he had been suffering for twenty-four hours with excruciating abdominal pain; abdomen was distended, and very tender over its entire surface. Blood count: Reds, 4,500,000; leucocytes, 16,000; 89 per cent. polymorphonuclears. He complained of great nausea and vomiting as well as prostration. The onset of the disease being very sudden, the rigidity of the abdominal muscles suggested peritonitis. Incision was made along the right linea semilunaris and an inflamed bowel presented itself. The patient, not being well anesthetized, coughed, when a large inflamed appendix, the apex directed upward, came into sight and was very easily removed. This was a case of the appendix directed upward and lying anterocecal, situated between the cecum and ascending colon and the abdominal wall.

Case VII. (Fig. 11)—Appendix directed along the cecum to the ileocecal valve and then lying along the ileum the rest of its course. Ethel L., aged 5

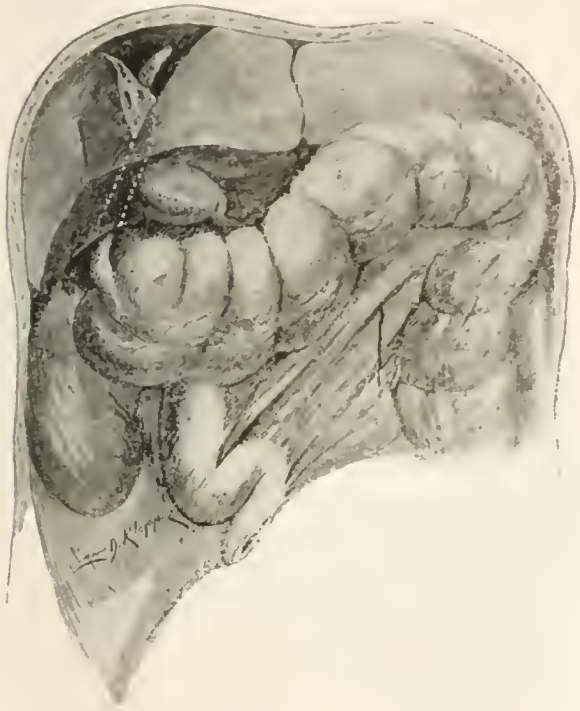

Fig. 10.—Case XIV: Non-descended appendix, tip back of the liver, suppuration resulting in a subphrenic abscess.

years, weight, 45 pounds. Had been entirely well until two days previous to entering the hospital, Jan. 18, 1907, at 2.00 P.M., when I first saw her in consultation with Dr. Hood. Temperature was 102°; pulse, 110; respirations, 30. For two days she had complained of abdominal pain, with nausea and vomiting. Diagnosis of appendicitis with localized peritonitis was made; she was taken to the Willard Hospital where the diagnosis was confirmed by operation at 3.30 P.M. The appendix was found extending along the cecum to the small intestine

Fig. 11.—Case VII: Appendix attached to the small intestine, inflammation causing intestinal obstruction.

and adherent to the cecum about two-thirds of its length. The appendix was removed and the abdomen drained with six strips of iodoform gauze. The patient progressed nicely until Jan. 29, when

the temperature rose to 102°; Jan. 30, the temperature at 8.00 o'clock in the evening was 103.6°. Blood count: Reds, 5,200,000; leucocytes, 24,000; polymorphonuclears, 79 per cent.; large mononuclears, 7 per cent.; ensinophiles, 4 per cent.; small mononuclears, 10 per cent. Palpation revealed marked ten-

Fig. 12.—Case IX: Non-descended appendix, tip adherent to the pancreas, suppuration resulting in acute pancreatitis.

derness in the left inguinal region, where the tumor could be felt. At 10.20 the patient was given a general anesthetic, chloroform being used, and an abscess in the left inguinal region was drained, the abscess extending into the pelvic cavity. The temperature gradually subsided, and the patient left the hospital well, Feb. 15, 1907.

Case VIII.—Appendix adherent to the cord in a right inguinal congenital hernia. Mr. L. Entered the West Side Hospital July 2, 1904. Complained of pain in the right inguinal region. Said he had a hernia, but that it was impossible for him to wear a truss because it produced pain, which was soon followed by nausea and vomiting. On examination, the incomplete inguinal hernia could be detected, and pressure over the cord caused pain. The following day he was anesthetized, chloroform being used, an incision was made for the Baccini operation, and upon coming to the sac and opening it the congenital hernia was found. The appendix, with a long mesoappendix, extended along the cord and was firmly adherent to it. The appendix was removed and the sac ligated and removed by the typical Baccini method.

Case IX. (Fig. 12).—A case of tuberculous pancreatitis secondary to tuberculous appendicitis. Miss Y., aged 7 years. Never well since one year of age, when she had some intestinal trouble. After she was old enough to talk she complained at intervals of pain in her stomach, and would locate the pain in the region of the gall-bladder. When she was 2 years old a diagnosis of intestinal obstruction was made. Cathartics were given and the obstruction was supposed to be relieved. She continued having the pain until two years ago, when she suddenly was taken with diffuse abdominal pains, nausea, and vomiting. This attack simulated the previous attacks, but was more severe. Her father is a physician, and in consulting some of his neighboring physicians a diagnosis of chronic appendicitis was made. She recovered from this attack and remained comparatively well for about a year. When first I saw her she was emaciated, complained of severe abdominal pain, nausea, vomiting; temperature elevated. Blood count: Reds, 4,000,000; leucocytes, 10,000; polymorphonuclears, 30 per cent.; small lymphocytes, 60 per cent. From the condition of the blood we suspected pancreatic trouble. The finding of pentose in the urine further assisted us in our diagnosis. She was taken to the hospital, anesthetized, incision made opposite the umbilicus at the linea semilunaris. The appendix was found extending to the pancreas, it was inflamed, and the head of the pancreas contained numerous hard nodules about the size of a buckshot. Many mesenteric glands were enlarged. Diagnosis of tuberculosis of the mesenteric glands and pancreas was made. The appendix was removed. The patient died two weeks later of general pelvic and abdominal lymphatic tuberculosis as well as a general tuberculous peritonitis, causing intestinal obstruction. Postmortem findings: The lungs contained old healed tubercular areas. The mesenteric lymphatic glands and pancreas were tuberculous. Operation was performed in the Christian Hospital, Valparaiso, Ind.

Case X. (Fig. 16)—Extraperitoneal appendicitis diagnosed for three days, renal colic. Mr. McC., aged 42. April 2, 1907, while moving a piece of stage scenery, was suddenly seized with pain in the lumbar region and was taken to a hospital where diagnosis of renal colic was made. He remained in the hospital two days, when he was transferred to the Frances Willard Hospital, where I first saw him. Having seen the patient in numerous attacks of a similar nature and having repeatedly made a diagnosis of appendicitis, I again advised operation,

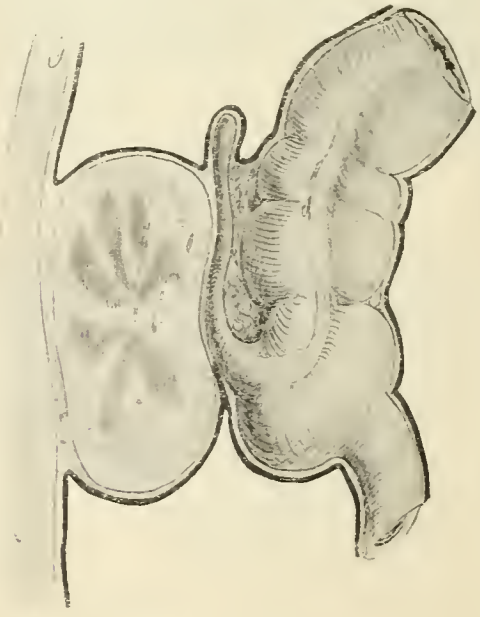

Fig. 13.—Normal appendix; body extraperitoneal; tip, above kidney, and base intraperitoneal.

which he accepted. He was taken to the operating-room at 4.00 o'clock P.M., and anesthetized, chloroform and ether being used. The temperature at the time of entering the operating-room was 98.8; pulse, 90; respirations, 20. Patient stated that the pain on the right side was almost unbearable, and

he had been vomiting almost constantly for two days. Incision was made at the outer border of the right rectus muscle, the center of the incision opposite the umbilicus. The cecum was found, but no appendix. Following the linear band of the large intestine, it was seen to go extraperitoneal.

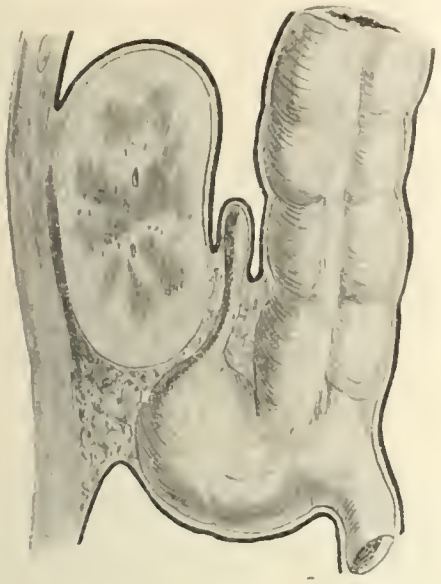

Fig. 14.—Normal appendix lying outside the peritoneum along the ureter.

The posterior peritoneum was incised and the band followed upward, when the appendix was discovered. Using my index finger through this opening the appendix was finally loosened and brought into the abdominal cavity and removed. The incision in the posterior peritoneum was closed with catgut, no infection being present the abdominal incision was closed by a continuous subcutaneous silkworm gut suture. Patient left the hospital at the end of the third week, and has had no pain in the right side nor in the abdomen since the operation, the longest period of time that he has been free from abdominal pain in ten years. This was a case of extraperitoneal appendicitis, the appendix being wholly extraperitoneal and its inflammatory condition exactly simulating renal colic.

Case XI. (Fig. 18)—Paranephritic abscess due to extraperitoneal appendicitis. Felix H., aged 39. On April 1, 1907, he was taken with severe pain in the right side radiating to the shoulder and down the arm. Said that a week previous to this he had had a similar attack that lasted only a few hours. He was seen by Dr. Hood, April 2, 1907, and was at once brought to the Frances Willard Hospital, where I first saw him. Diagnosis of appendical abscess was made. He was taken to the operating-room at 5.15 P.M. Temperature at this time was 99.4°; pulse, 82; respirations, 30. Reds, 4,500,000; whites, 29,000; 90 polonuclears. An incision was made on the right side at the outer edge of the rectus muscle, the middle of the incision opposite the umbilicus. The cecum was found, the appendix was diseased, and a large abscess was lying back of the ascending colon. The appendix was removed, a counter opening made in the back and through and through drainage was established, a soft rubber tube being used in addition to several strips of iodoform gauze. The patient made an uneventful recovery, leaving the hospital at the end of the third week.

Case XII. (Fig. 18)—Mrs. R., age 32 years. Irish, married. Has one child living and well, age 2 years. When the patient was 2 years of age she swallowed a pin. In about two months she complained of pain in the right inguinal region. An abscess formed, was opened by a local surgeon and the pin was removed from the abscess cavity. The sinus remained which refused to heal under all treatment. This persisted for 30 years when she decided to have an operation to cure a fecal fistula. At the operation the tip of the appendix was found grown to the abdominal wall and the lumen of the appendix formed a sinus. All that was necessary to cure the fecal fistula was to remove the appendix.

Case XIII.—Tuberculous appendicitis. Miss H., aged 20, nurse in training. March 4, 1907, was seized by diffuse abdominal pains. Blood analysis at this time: Hemoglobin, 85 per cent; reds, 4,250,000; leucocytes, 4,600. She remained in bed two days, by which time she had markedly improved, and she arose and went to work. March 10 she complained of feeling great discomfort in the abdominal cavity, claiming that she was bloated. Another blood count was ordered: Hemoglobin, 50 per cent; reds, 4,150,000; chucocytes, 7,200. March 11 she complained of excruciating abdominal pain which localized in the region of McBurney's point. The abdomen was still markedly distended; temperature, 97.8°; pulse, 110; respirations, 26. An exploratory laparotomy was advised and accepted. At 7.30 P.M. she was anesthetized, chloroform being used, incision was made over the region of the appendix, a large quantity of fluid escaping through the incision. The small intestines were coiled upon themselves in an S-shape and adherent, producing an intestinal obstruction. The appendix was diseased and adherent to the small intestines. The intestines had a moldy appearance, and a diagnosis of tuberculous peritonitis as well as of appendicitis was made. The appendix was removed, the intestines exposed to the air, drainage established by strips of iodoform gauze, and was free for several weeks. Through the kindness of Dr. Clark, she was

Fig. 15.—Normal appendix; the tip surrounded by peritoneum, the base not invested by serous membrane.

given tuberculin every tenth day. She made a slow but steady recovery and left the hospital June 18, and writes us from her home that she has regained her strength and apparently is entirely well.

Case XIV. (Fig. 10)—Intraperitoneal nondescended appendix, the tip lying between the liver

and the diaphragm, the condition simulating pleurisy. Mr. P. Entered the Frances Willard Hospital April 26, 1907. Said that for thirty-six hours he had suffered excruciating pain localized on the right side in the region of the gall-bladder, also had excruciating pain on deep inspiration. Blood count:

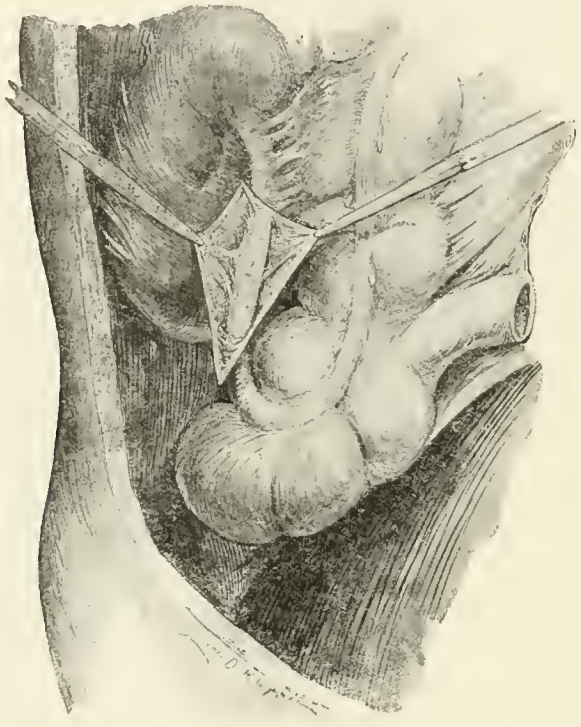

Fig. 16.—Case X: Nondescended extraperitoneal appendix lying along the ureter, suppuration resulting in perinephritic abscess.

Reds, 4,600,000; leucocytes, 23,000; polymorphonuclears, 88 per cent; temperature, 99.6°; pulse, 68; respirations, 24. Deep pressure continued along the linea semilunaris caused pain in the region of the liver and increased tenderness. There was pain in both the right and left lumbar regions. Diagnosis of gangrenous appendicitis was made and confirmed. The cecum was very short, the appendix lying well back of the liver between the liver and the diaphragm. The appendix was removed and strips of iodoform gauze were placed between the liver and the diaphragm for drainage. Patient made an uneventful recovery and left the hospital at the end of the third week.

I have cited a few of the rare cases which have come under my observation. A record of these cases can be found in the files of the West Side Hospital and the Frances Willard Hospital, Chicago.

The diagnosis of the different forms of appendicitis should be readily made, and radical treatment at once advised. The diagnosis of nondescending appendicitis simulating gall-bladder trouble or pancreatitis, etc., cannot be readily diagnosed. Only by careful and systematic examination can a diagnosis be made.

The three painful points of appendicitis are: (1) In the region of the appendix on deep palpation, (2) in the region of the right, and (3) left lumbar plexus on deep palpation. Pressure on these points will produce pain in the region of the gall-bladder in a nondescending appendicitis which irritates the gall-bladder. Pressure on the above points does not produce pain in simple hepatic or gall-stone colic. The same can be said of acute suppurative or gangrenous nondescending extraperitoneal appendicitis, simulating renal colic; pressure in the regiion of the kidney produces pain, but this pain can be traced to the three regions of pain in acute gangrenous or suppurative appendicitis. Diabetes accompanying a nondescending appendicitis suggests pancreatitis.

Varieties of Appendicitis. *Acute Catarrhal.*—The variety of appendicitis that has most frequently come under my observation and is most common, is the acute catarrhal form; the attack is sudden, with diffuse abdominal pain, rigidity of the abdominal muscles, nausea and vomiting, pain localized in twenty-four hours at the appendix, moderate temperature, fever ranging from 100° to 102°.

Etiology.—The cause may be from without or from within the appendix; if from without it is usually due to adhesions extending from some surrounding organ; again, it may be due to intestinal disturbances, foreign bodies, endoliths or gallstones, these conditions occurring without infection. The patient may be relieved in a few days and have no further symptoms, the blood count indicates nothing alarming, and there is practically no change. The *treatment* is to clean out the bowels with laxatives and enemas, giving no food for at least twenty-four hours. If the symptoms increase and the temperature becomes high and the pulse rapid, accompanied with a gradual increase in the number of leucocytes as well as an increase in the polymorphonuclears, the case is no longer one of catarrhal appendicitis, but indicates gangrenous or suppurative appendicitis in which immediate operation is always advisable.

Acute Suppurative.—This form of appendicitis comes on suddenly and may be the initial attack, but usually is preceded by repeated attacks of catarrhal appendicitis. There is diffuse abdominal pain starting in the region of the umbilicus and rapidly spreading over the entire abdomen, accompanied by

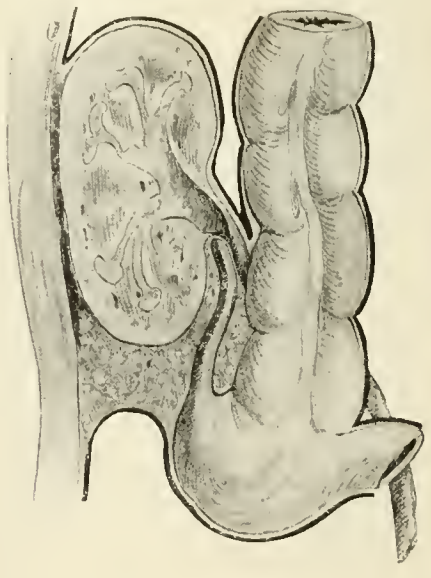

Fig. 17.—Case XI: The normal appendix, lying entirely outside the peritoneum.

nausea and vomiting, and rise of temperature, 103 to 105, occurs within twenty-four hours. The pain usually localizes in the region of the appendix with rigidity of the abdominal wall, more marked on the right side than on the left, pulse is increased and bounding (patient has an anxious expression or the facies of one suffering excruciating pain), the thighs are flexed up on the abdomen, the patient frequently lying on the right side.

Etiology.—Foreign bodies such as enteroliths, gallstones, pins, needles, intestinal parasites, hair, fish-bones, and grape-seeds, or any foreign body that may have entered the alimentary canal, may cause the condition. It may be due to infection from without, such as pyosalpinx, prostatitis, or any intestinal or pelvic inflammation.

Treatment.—This is always surgical, and operation should be performed just as soon as a positive diagnosis is made. Termination without operation may be by rupture into the cecum, or extraperitoneal, in the latter case forming a perinephritic abscess; pus may be absorbed and calcareous deposits formed, resolution may take place without calcification, but death is usually the final termination. A blood count shows a rapid increase in the number of leucocytes as well as in the polymorphonuclears

Gangrenous.—The symptoms are those of either acute catarrhal or suppurative appendicitis. The patient may continue to work for a day or two, but the pain gradually localizes, and not until there is

Fig. 18.—Case XII: Appendicial abscess two months after the swallowing of a pin; the pin was removed, but a fecal fistula persisted for thirty years; the tip of the appendix was adherent to the skin, the lumen forming the tract of the fistula.

an absorption and a localized peritonitis does the patient cease work or call a physician. When there is marked and rapid gangrene the temperature is normal or subnormal, tongue dry and coated, nausea and vomiting, constipation, the face pale, with an anxious expression. The cause of this form of the disease is usually due to adhesions following frequent attacks of catarrhal appendicitis, the adhesions gradually contracting until the appendix is bent upon itself and is strangulated, the blood supply cut off from a portion of it. This condition may also be due to an ovarian cyst, tumors from without, or foreign bodies from within.

Pathology.—Lack of blood supply, leucocytes may go as high as fifty or seventy thousand with a high percentage of polynuclears and a marked increase in the number of eosinophiles, although I recently operated on a case of marked gangrenous appendicitis with a leukopenia, the patient having only five thousand leucocytes.

Termination.—Nearly always fatal if not operated.

Tuberculous Case XIII.—The symptoms are usually not severe, and simulate chronic catarrhal appendicitis. The temperature is usually elevated at night. There is loss of flesh and later the formation of acitic fluid, which is often the result of tuberculous adnexa-uteri, or may be secondary to tuberculosis any place; in the male it may follow tubercular epididymitis, pulse usually rapid and weak, and there is little blood change.

Treatment.—This is surgical, removing the appendix and other diseased organs if possible, followed by use of tuberculin and other antituberculous remedies after recovery from the operation.

Termination.—Recovery, or may be followed by grangrene or acute diffuse tuberculous peritonitis.

Appendicitis Obliterans, or neuroma of the appendix, is usually found in people past the middle age of life, but usually follows repeated attacks of catarrhal appendicitis or a low grade suppurative appendicitis if terminated by absorption or calcification.

Symptoms.—Simulate those of chronic appendicitis or appendiceal colic; there may be nausea and vomiting; pain is usually localized in the region of the appendix not diffuse; pulse is unchanged, blood count negative; constipation is usually present, which is the most common symptom aside from pain. On examining the appendix it is found to be a mere cord or white line, the lumen obliterated. Under the microscope it is shown to be composed almost entirely of fibrous tissue. Contraction and squeezing of the nerves elicits pain similar to that produced by a neuroma.

Technique of Examination.—Correct diagnosis cannot be made without a careful, painstaking and systematic examination. The patient should be divested of all clothing and placed on the back, the abdomen should be exposed and the palms of the examiner's hands should be placed upon the abdomen, one on the right side and one on the left, and equal pressure made so as to elicit the rigidity of the abdominal wall and enable one to compare the rigidity of the right side with that of the left. Only in this way can the rigidity of the abdominal wall be elicited. In conjunction with this the shoulders and head should be slightly raised, the thighs slightly flexed, and the patient instructed to relax the muscles of the abdominal wall as much as possible, and breathe through the open mouth; at the same time the patient's attention should be attracted to the left side and if the right rectus is more tense than on the left the fingers on the left side will sink into the abdominal wall while those on the right side will meet firm resistance. Palpation in this manner should not be limited to the lower abdominal wall, but should be systematically performed over the entire abdomen, and should be discontinued as soon as pain is elicited. After the painful points have been carefully noted, then we should go back to the original point of palpable pain and make deep pressure over the particular point and continue this pressure until it is discovered whether the pain is transmitted from the region of the palpable pain to the region of the pain complained of by the patient; if the pain is transmitted from a point not complained of by the patient to a point distant, then one is quite safe in concluding that the pain is reflex. If, although the patient may not complain of any pain in the region of the base of the normal appendix, by deep, constant pressure over this point pain is elicited in the region of the kidney, gall-bladder, right or left pleural, or right or left inguinal or hypochon-

driac regions, we are justified in supposing that the patient has a reflex pain due to an irritation produced in the region of the cecum, and all precautions should be taken to prevent the disaster that often follows delay in making a diagnosis and operating acute suppurative or gangreuous appendicitis.

Summary.—1. Catarrhal appendicitis should be considered a surgical disease. A cessation of pain does not always mean an improvement. A differential blood count should be made every four hours. If there is a gradual increase in the number of leucocytes, accompanied with an increase of polynuclears, the case is no longer catarrhal but suppurative or gangrene, and operation should be advised regardless of pain, temperature and pulse. Females should be operated early in the first attack of appendicitis and under no circumstances should a case be allowed to become chronic, for in the vast majority of cases the right ovary and tube soon become diseased. Pregnancy frequently is accompanied by gangrene of the chronic catarrhal appendix and many cases of puerperal sepsis are placed at the door of the obstetrician which are only recurrent attacks of appendicitis following labor.

2. Acute suppurative appendicitis is always surgical and should be operated without delay.

3. Gangrenous appendicitis is always surgical and should be operated early before there is thrombosis of the mesenteric vessels. A subnormal temperature with slow, bounding pulse and gradually decreasing pain, is indicative of grave toxemia and the forerunner of dissolution.

4. Tuberculous appendicitis is seldom primary, but is always surgical, and may require extensive resection. If the pancreas is nodular there is probably secondary infection of the pancreas, and death usually follows from general tuberculous infection.

5. Appendicitis obliterans caused by repeated catarrhal attacks resulting in a fibrous obliteration of the appendix including the mesoappendix, causing a neuroma of the appendix and mesoappendix. The condition is always surgical.

6. Appendiceal abscesses are located in the region of the appendix and do not locate in regions distant from the appendix.

7. Appendicitis must be diagnosed from cystitis, pyosalpinx, pyelitis, pancreatitis, pyloric obstruction, duodenal ulcer, hepatic colic, subphrenic abscess, subhepatic abscess, pleurisy, and pneumonia before operative procedure is recommended. A correct diognosis can be made if the symptoms and findings are studied together with the urinalysis and differential blood count.

8. Patients may have appendicitis at any age. I have recently operated in a case of gangrenous appendicitis in a baby six weeks old. The patient was brought to me by Dr. C. King.

9. I am indebted to Dr. B. J. Orndoff for the laboratory reports.

Recovery from a Brain Tumor.—Camillus Bush has reported a case of glioma of the brain on which he did a decompression operation with marked improvement. Later the symptoms recurring, a second operation was done and a large cyst found. This was tapped several times and finally freely opened. The patient appears to have made a good recovery. Dr. Bush calls attention to three points: (1) the remarkable disappearance of the tumor through cystic degeneration; (2) the fact that operations on the brain itself can be carried on without anesthesia; and (3) the apparent location of the center for the steriognostic sense in the pre- and post-central convolutions.—*California State Journal of Medicine.*

NOTES ON THE SANITATION OF YELLOW FEVER AND MALARIA. FROM ISTHMIAN EXPERIENCE.*

By H. R. CARTER,

SURGEON, U. S. P. H. AND M. H. S.; DIRECTOR OF HOSPITALS, ISTHMIAN CANAL COMMISSION.

I am asked to write of some "Recent Advances in Tropical Sanitation." There are only two tropical diseases, the prevention of which I can discuss at first hand: Yellow Fever and Malaria. Indeed, I am not even aware of any noteworthy advances in the methods of preventing these two which have been made recently; yet, as that term is comparative, it may be that in the first, at least, I can bring something to your attention worthy of consideration, and even in the second, for which I surely have nothing new, a statement of the conclusions to which we have come, and the methods we have used on the Isthmus, and the reasons for them, may be of interest.

YELLOW FEVER.

Since two hosts, one human and one insect, are necessary for the propagation of yellow fever, it is obvious that a perfect control of either is sufficient for the elimination of this disease from a community.

If every person developing yellow fever was immediately isolated from the stegomyia mosquito (*i. e.* no access was allowed to him while he was in an infective stage by stegomyia), yellow fever would inevitably cease. Similarly, if there was no access to men (I mean men susceptible to yellow fever), by any stegomyia in the infective stage, the same thing would occur. Theoretically, then, we can eliminate yellow fever by control of either the human or the insect end of the chain.

At which end of the chain shall we begin? Shall both be tried at the same time? They are not incompatible.

At first sight it seems most feasible to try to control the human host, because (1) we can tell, more or less, when he develops yellow fever; (2) when found we can isolate him, by wire screening or otherwise, from mosquitos; (3) the period of infectivity of the human host is very short, three or four days at most, during which time only he need be guarded.

On the other hand, stegomyia once infective remain so indefinitely, and, except as their environment creates a presumption that they have or have not had access to a man in the infective stage of yellow fever, we have no means of telling an infective stegomyia from any other, and the only practicable means of control of the insect host is by its extermination—more or less complete.

The destruction of the stegomyia mosquitos, which have had access to a man in the infective stage of yellow fever, as distinguished from the general destruction of stegomyia, requires such a knowledge, and hence control, of the human host, as to place this measure in the class of those determined by the control of the human rather than in that of those determined by the control of the insect host, and it is so considered in this paper.

It seems easier, then, and more natural to attempt to control the human host; and the first attempt to exterminate yellow fever after its method of propagation was known, which was so brilliantly carried out by Gorgas at Havana in 1901, mainly rested on this method. The attempt to lessen the

*Read at the Section of Hygiene, Pan-American Scientific Congress, Santiago de Chile, December, 1908.

number of stegomyia by destroying their breeding places was also made, and made vigorously, but the principal dependence was placed on the isolation of the infected men, and the destruction of the mosquitos already infected by him; the destruction of stegomyia in general being regarded as adjuvant to the main work.

The same methods were used by Liceaga for Vera Cruz; by White for New Orleans, and finally by Gorgas for Panama and Colon. Its general adoption, then, shows this (the first method thought of) to be the most natural one. Yet Gorgas now believes, and I think all who participated in the work here concur with him unreservedly, that his success in Havana and on the Isthmus was due to the war waged against the stegomyia directly by the destruction of their breeding places, undertaken as an adjuvant to the isolation of the sick, rather than to that isolation itself; to the control of the insect rather than of the human host (See "Method of Spread of Yellow Fever," by W. C. Gorgas, MEDICAL RECORD, June 27, 1908).

The reason that the method by control of the human host failed was because, under the conditions that existed, it was impossible to carry it out. *We could not control the human host* to the degree necessary for success. No one who has conducted a campaign against yellow fever in a place where it was endemic, where the inhabitants do not fear it, can imagine the difficulties of finding the cases of yellow fever early in the disease, or at all, even the cases which are plain. For the light cases let me say this: an analysis of the yellow fever statistics of Havana for the ten years preceding 1895, published by me in 1900, in the United States Public Health Reports, led me to state that but a small proportion of the cases of yellow fever in adults in Havana, about one-eighth, I think, had been diagnosed. Taking this into account, in addition to the cases in native children, which are practically never diagnosed (I quote Gorgas again), and I think the most optimistic will admit that in such places control of the human host to a sufficient degree to eliminate yellow fever is impossible—not difficult, but impossible. Our only hope, then, is to control the insect host, to destroy the stegomyia.

Let me say here that the conditions are by no means the same in a town in which yellow fever is not endemic, where its has only recently been introduced, and has not become generally epidemic. On account of the limitation of area in which infection exists (especially is this true of a small town) and the help one can count on from the citizens, we have much more control of the human host, and it can be made sufficient to eliminate the disease. This was, I believe, the decisive factor in the suppression of the New Orleans epidemic by White. Although a most vigorous war was waged against the breeding places of stegomyia, the most vigorous of which we have any record, the results were too quick, in my opinion, to be due to the gradual extermination of the stegomyia by failure of their breeding places. This was certainly the only method used in the suppression of a little epidemic in McHenry, Miss., in 1898. The method of the conveyance of yellow fever was not then known, and some unnecessary things were done, such as disinfection of clothing, but every case of yellow fever was isolated in tents, pitched in a pine forest, as soon as it developed (every person in town being seen twice a day), and the house and the adjacent houses fumigated at once. No attempt was made to destroy the breeding places of mosquitos. The epidemic, which was well under way when discovered, lasted about six weeks after work was begun. The same result was obtained by the same methods in the epidemic at Hampton, Va. (White and Van Ezdorf), but more quickly, in about two weeks, because the method was better carried out.

For yellow fever, then, in towns where it is not endemic, and not generally epidemic, an attempt to control the human host should, in general, be made. If the people of the town are intelligent and will cooperate it should always be made, more especially if the place be small, or the infection be limited to a small area. In any case it will limit the rapidity of spread of the disease, and greatly diminish the damage it will do until the more radical measure of extermination of the insect host has been accomplished by destroying its breeding places, a thing which should also always be pressed from the beginning. I have seen a number of places in which this method, without ridding the town of yellow fever, has so far lessened its rapidity of spread that it has been able to tide over six weeks or two months with a minimum amount of fever cases cropping up here and there until frost put an end to it.

On the other hand, were the problem to rid of yellow fever a town in the tropics in which it is endemic, as say Guayaquil, I would concentrate all my energy in ridding the town of stegomyia; I would not isolate those sick of yellow fever, save possibly as a protection to those in the immediate neighborhood. As a measure of general sanitation, helping to rid the town of yellow fever, its value would not pay for the trouble it causes, if indeed it had any value at all for this purpose.

The conditions of the two classes of places are different, and the means advisable for the riddance of yellow fever are also different. For the last, control of the insect host alone is to be aimed at; for the first, control of the human host should also be vigorously pressed.

Obviously, the elimination of yellow fever by the removal of the insect host places the town in a far more advantageous condition than if this result was accomplished by control of the human host alone, as in the former case it has become what is known as "noninfectible territory," and as long as it is kept in this condition no defence of quarantine, or otherwise, against the introduction of yellow fever is needed. In such a town yellow fever is no more communicable than sprained ankles, and the town is safe from it. Unquestionably this is the condition to which all sanitarians wish it to attain.

I will add here that the domiciliary sanitary measures involved in finding the sick, in isolating them, and in fumigating the houses to destroy the mosquitos which have had access to them even if it be successful, is many fold more difficult, costly and troublesome than the work against the breeding places of the stegomyia, and also in a town in which the disease is endemic it excites infinitely more opposition from the town's people. It is hard to estimate the boon it is to the working sanitarian to be able to abandon such methods.

The abandonment, then, of the attempt to control the human host, and the concentration of all effort on the destruction of the stegomyia mosquito, is a distinct advance in the methods of freeing a town, in which yellow fever is endemic, of that disease. It is hardly necessary to say that the sanitation for yellow fever of towns in which it is endemic should begin with the introduction of the water supply in

pipes, so as to do away with the necessity of storing water in cisterns, rain barrels, jars, etc.

It may be noted here that the disappearance of yellow fever in Panama followed close on the breaking of the connections of the gutters with the cisterns, so as to let the rain water from the roofs out on the street. We found that even when the roof gutters, on account of so frequently being flushed out by the rains, bred no stegomyias, yet the cisterns, perfectly screened as they were, did breed stegomyia in quantity from the eggs and larvæ washed down to them from these gutters. The mosquitos escaped into the house every time the trap door was opened in the house to draw water, and the only safe cisterns were those that were not only covered and screened, but that delivered their contents only through a pump. This was the last measure taken against the breeding of stegomyias prior to the disappearance of yellow fever. It is better, of course, to have no gutters, or gutters so short and steep as to hold no water.

MALARIAL FEVER.

I doubt if I have anything new to bring to your attention here. As malarial fever, like yellow fever, requires two hosts for its propagation, the same remarks as to its elimination from a community by the perfect control of either host apply to it as have already been made in the case of yellow fever. It is, however, a much more difficult problem.

It is much harder to get rid of anopheles than of stegomyia, the breeding places of the latter being practically confined to artificial containers and in the neighborhood of human habitation, are much more easily destroyed than those of anopheles, which breed in marshes and in any pool or stream in the grass or bush. Their breeding places then cover a much larger area, frequently the whole country, are far harder to find and harder to destroy when found than the breeding places of stegomyia; also this insect travels much farther from its breeding place than the stegomyia does, probably from three to four times as far. The insect host, then, is much harder to control.

It is also harder to control the human host. A man sick with yellow fever is infective to mosquitos only a few days, three or four; one with malarial fever may be infective, if not indefinitely, at least for a long time. Also the prevalence of the plasmodium in the cutaneous circulation of the natives of malarial countries (this is true also of foreigners who have lived in such countries for some time) without symptoms of malaria, renders attempts to suppress malaria by isolation of the human host impracticable, and I think not even to be considered, and, in spite of the opinion of so eminent a man as Koch, I doubt if any sanitarian would be willing to attack the problem in the American tropics exclusively from the end of the human host.

The effort then must be made mainly from the insect end of the chain, and we aim primarily to get rid of the anopheles by the destruction of their breeding places, but we will need also every adjuvant that we can use in our fight with this disease, and after all we will very likely, for any reasonable expenditure of time and money, be content with such a control of malaria that it does not cause sickness or mortality beyond what is allowable from an economic or humanitarian standpoint. This is possibly now the case on the Isthmus, and if we can reduce the malarial rate to, say, fifty per cent of its present amount, and this ought to be possible, we will be satisfied. No one would be satisfied with such a partial success with yellow fever.

Our methods here are: (1) To prevent the breeding of anopheles by destruction of their breeding places.

(2) To kill their larvæ in such breeding places as we fail to destroy.

(3) To prevent the access to the men we would protect of such anopholes as exist in spite of the above attempts to destroy them.

(4) So to arrange it that those anopheles, which, in spite of No. 3, do have access to the men we would protect, have not had an opportunity of becoming infected with malaria.

(5) So to immunize our men against malaria that even if bitten by infected anopheles they may not develop malaria.

Any one of the above methods perfectly carried out would be sufficient. It will be noticed that these methods are intended each one to supplement the failure, or at least the imperfect success of the preceding one, if (1) were absolutely carried out there would be no need of (2), (3), (4) or (5), and so for each one in its order. In practice here none of them can be entirely carried out, and there is need of all.

The first two aim to destroy the mosquito; the third to prevent contact between the two hosts; the fourth and fifth to render that contact harmless, (a) by preventing infection of the insect, or (b) by immunizing the human host against infection. These measures, I think, then, embrace every class of antimalarial work possible and allowable to us in this country.

The first three, which are the most important, are distinctly antimosquito measures, working from the insect end of the chain; the fifth is from the human end.

(1) In the destruction of breeding places; filling up low places, and tile draining hold the first places as permanent work. Drains lined with cement come next, and then rock-filled and open ditches.

A place suitable for filling and filled properly is permanently destroyed for a breeding place. This method is too costly for general use here.

Tile drains are not absolutely permanent, being liable to invasion by roots of brush, etc., but so far have given the best results of any method used on the Isthmus, counting both cost and efficiency. On account of its low cost of maintenance, as it is the best, it is probably, in the long run, the cheapest of the drainage methods, where applicable.

Cement lined ditches are expensive in their first cost, but the cost of maintenance is low, and in many places they are more economical, as well as more efficient, than open ditches.

Ditches filled by rocks, under and among which the water flows, have given good results, and are both cheap and reasonably permanent.

Open ditches are, of course, much the cheapest of all in first cost, but require constant attention, choking with grass and washing into holes, etc.

Open ditches and then tile are the mainstays of the sanitary department here for this work, but each of the five methods has its peculiar field of preferable use.

The introduction of fish into the pools and streams is also done in suitable places, and may be a permanent work, or fairly permanent work. The value of fish in open ditches is of less value here than in temperate countries, as both grass and algæ grow very rapidly here, and in their presence fish

are not to be depended on to keep a pool free from larvæ.

(2) To kill the larvæ in their breeding places, we use either coal oil or phinotas oil. The use of coal oil for this purpose is too well known to discuss; the latter is a poison to the larvæ, and acts on a different principle. In pools of large area, but shallow, where on account of the effect of wind and the growth in the water coal oil is inapplicable, and in some other conditions the phinotas oil is efficient where the coal oil is not. It has given good results also when a small stream has a number of small pools where also coal oil is unavailable. It is, however, of very variable composition, and one invoice differs from another in efficiency. I will mention here that the continuous use of both these agents discharged very slowly through a hole in a bucket suspended over the source of the water has, under certain conditions, given us most excellent results, saving tenfold in labor the extra use of material which this entails.

(3) Under the third head, "To prevent the access of the anopheles to the man we would protect," the methods in use are:

(a) Clearing off the bush, high grass, etc., around dwelling houses which would furnish a shelter to the insects. This must also cause the destruction of a number of mosquitos, as they cannot live in the hot sun. The cutting of the brush is a protection of value. There is no use in cutting grass unless it be long. The expense is too great for the benefit obtained.

(b) Screening the dwelling houses. This is of very great value, beyond all comparison greater than the removal of brush. In spite of the asservations of British writers the mosquito bar has not been, I think, of great value on the Isthmus. In the early days we all had them and used them most conscientiously, yet few of us escaped malaria. With the narrow beds in use, and the high cots, the bar gives imperfect protection, especially to a restless sleeper. How bad it might have been if we had not used them I cannot tell. Screened houses, however, are safe to careful and intelligent people. It is very much better to screen the galleries than only the doors and windows. The screen doors should open outwards, and the door should not be in a strong artificial light, but as much in the shadow as possible, so that mosquitos will be less liable to gather on it, and thus come in when it is opened. Regulations for screening the quarters, etc., were promulgated by the Chairman of the Isthmian Canal Commission in 1906, based on the report of a board of which the writer was chairman, and are in force for Commission buildings.

(4) To prevent the infection of the mosquitos which have access to the men we are protecting is simply to segregate the quarters of these men from those of the natives and colored laborers—a source of infection to the insects—a sufficient distance—which thing has been inculcated by the British writers for years. It is what is hardest to accomplish on the Isthmus of any of the measures we attempt, yet it is fairly important and considerable sickness has been occasioned by failure to observe this principle.

(5) When, in spite of the above mentioned measures, anopheles still have access to men, we attempt to immunize, or at least lower the susceptibility of, the men exposed.

This is by the use of moderate doses, grains three to grains six per day, of quinine. The effects of this method of preventing malaria have recently been attacked and the writer wishes that the limits of this paper allowed him to discuss the matter. He freely admits that we have been unable on the Isthmus to make such comparative observations, such as taking alternate men, living under the same conditions, one set receiving the phophylactic regularly and for some time, and the other not, as would, after a reasonable number of trials, amount to a demonstration; yet the rapid fall, the invariably rapid fall of the percentage of malaria in the camps where the prophylactic quinine is given regularly, has occurred so many times that the evidence from the Isthmus must be regarded as strongly in its favor. So many factors come in, however, that it would require a very large number of observations such as we have made here to be conclusive. I know of no physician, however, on the Isthmus who has tried it for any length of time on a large scale who does not regard it as a valuable adjuvant in preventing malaria and rendering it milder and more amenable to treatment when it occurs. There are a few people, very few, I think, who cannot take even the small doses required; quite a number who object to it and do not take it. Most people, however, can take it indefinitely without any perceptible effect on their general condition.

Quinine as a prophylactic is not taken regularly and generally by the employees of the Commission. When the malarial rate is low the men become careless, and the proportion of those who avail themselves of it is small; especially is this true of the laborers. When the malarial rate is high at any point, however, extra effort is made to administer it, and in the presence of much sickness, the men take it. The men who have been here some time take it readily; the white men, who have been through other malarial epidemics ask for it. Some of the best results in bad epidemics have been obtained by comparatively large doses of quinine, eight or ten grains per day, and then dropping off to four or five. This was when the camp was pretty generally infected, the men generally having malaria in larval form, and was intended as something more than prophylactic.

This is probably the place to draw attention to the cooperation between the Hospital Division and the anopheles work, which is of decided advantage to the latter, as it is also a "method" for the control of malaria. Every week a report is made of every camp, giving both the number of malarial cases sent to hospitals from such camp and the percentage this bears to the number of employees. From this the Chief Sanitary Inspector can see (1) the rise and fall of the malarial sick rate at any place, and (2) the comparative malarial rate at different places, and while many factors enter in determining this rate, yet the presence of anopheles is one of them, and this report gives him a clue where he should concentrate his efforts, where good and efficient work is being done, and is of great advantage in inciting the spirit of friendly competition among the subordinate inspectors directly in charge of the work.

Eyes of School Children.—After an extensive study of the eyes of school children in London, N. Bishop Harman concludes that "there is no evidence on which to base a pessimistic attitude towards the general tendencies of a healthy school life in so far as the condition of the eyes of the child population is concerned."—*Proceedings of the Royal Society of Medicine*

THE IMPORTANCE OF THE EARLY RECOGNITION OF BONE TUBERCULOSIS.*

By ARTHUR J. DAVIDSON, M.D.,
PHILADELPHIA.
INSTRUCTOR IN ORTHOPEDIC SURGERY, JEFFERSON MEDICAL COLLEGE.

Rarely does the orthopedic surgeon have the opportunity of seeing the starting point of the diseases that are so often referred to him for treatment. Especially rarely is he called to see a patient suffering from bone or joint tuberculosis when the very first symptoms present themselves; this being the time of greatest importance, the time when treatment is most efficient, when the disease is most easily checked, and when much suffering and unsightly deformity can be prevented.

Is it not the family doctor, the general practitioner, who is first called to see the patient? Is it not he who sees the disease in its most incipient stage, and is it not he who should be most impressed by the great importance of its earliest recognition? It is with this view in mind that this paper has been prepared as an appeal to the general practitioner, that he may not overlook such seemingly trivial symptoms as night cries, so-called "growing pains," stomach ache, and many other apparently unassuming evidences of such an important disease; and that the presence of these symptoms may be conductive of more critical examinations and more exacting observations so as to exclude, among other affections, bone tuberculosis.

The extreme importance of this subject can be appreciated only by one who daily comes in contact with the miserable examples of a "too late" diagnosis and a neglected treatment. The shortened limb, the stiffened and distorted hip, and the hunched back all could have been prevented had the disease been recognized in its incipiency.

It is not my object or intention to place the blame upon the family doctor, or to accuse him of negligence, tardiness, or lack of diagnostic ability. The triviality of the symptoms is often such that the parents of the child deem it unnecessary to seek medical advice and treat the child with simple home remedies until, finding them of no avail, consult their doctor. It is at this time, the disease being now fairly well advanced, that the responsibility is thrust upon his shoulders, as it now befalls his lot to make the first diagnosis, the turning point regarding the future of the case.

Tuberculosis is now the subject of especial interest both to the medical profession and to the community at large. Great strides have been made and greater strides are being made by physicians the world over in stamping out of existence pulmonary tuberculosis. Medical journals and even newspapers are filled with articles relative to this subject, yet little mention is made of bone tuberculosis. It is an appalling fact, but nevertheless a true one, that the average layman has never heard of the disease. He sees and passes on the streets the poor cripple, the living monument of what might not have been, yet little does he think of the disease that causes the dreaded deformity.

In orthopedic circles, however, much work has been done along these lines, nevertheless bone tuberculosis is an exceedingly prevalent disease. For its eradication there is needed and desired the public interest as well as the earnest and willing cooperation of the general practitioner.

*Read at a meeting of the North Western Medical Society, Philadelphia.

It is indeed a very simple matter to diagnosticate hip-joint disease when there are present such symptoms as ankylosed hip, shortened and atrophied leg, an abscess or a discharging sinus. But of what value is it to the patient to have his or her condition recognized after the damage is done? It is true that even at this time, proper treatment being resorted to, the disease may be checked, but even so, the shortened and wasted leg will never regain its normal dimensions nor will the ankylosed or eroded joint functionate as before. For these reasons alone, the great importance of the earliest symptoms of this most insidious disease, bone tuberculosis, must become manifest to every medical man, and it should become his duty to acquaint himself with these symptoms, that he may more easily recognize the disease.

A few of the more important facts regarding the etiology of bone tuberculosis may be considered before taking up the subject of the early symptoms. Tuberculosis of bone and joint is preeminently a disease of childhood. It is not congenital and is uncommon under one year of age. It is most common between the ages of three and ten, but may occur at any age. Sex is not a prominent factor, boys being slightly more affected than girls. Any joint in the body may be affected. The combined statistics of Cheyne, Jaffe, Schmalfuss, Bilroth, and Menzel, covering 919 cases, indicate the relative frequency with which the various joints are affected as follows: Spine, 23.2 per cent.; knee, 16.5; hip, 14.6; tarsus, 14.4; elbow, 6.3; wrist, 6.0; skull, 5.5; sternum, clavicle, and ribs, 5.2; pelvis, 3.5; femur, tibia, and fibula, 3.5; shoulder, 1.5; scapula, ulna, and radius, 1.0; humerus, 0.8; patella, 0.1.

It has long been claimed that heredity was a factor in causing joint tuberculosis. Whether or not the bacillus of tuberculosis can be directly transmitted from parent to offspring is still an open question, but that the surroundings of certain families weaken the resistance and favor tuberculosis invasion seems to be a well grounded fact. It is almost impossible to attempt to show the proportion of children suffering from joint tuberculosis that inherit this tendency. In the class of patients from which statistics come, anything approaching accurate information in regard to family history can hardly be expected. There is a strong inclination to deny and conceal any history of tuberculosis in members of the family, and a tendency to establish a traumatic cause for the affection of the joint instead of having it supposed that the child inherited any constitutional predisposition. On the other hand, it must be remembered that in a community in which approximately ten per cent. of all deaths are from tuberculosis, it stands to reason that this disease must of necessity appear in the family history of a certain proportion of our cases. It only goes to show how inaccurate our statistics must be, but, be it as it may, the error is likely to lie always on one side, in underestimating and making the proportion of inheritance too small.

From one-sixth to one-half of all cases appearing in collected statistics would seem to have a traumatic origin. The most recent statistics based upon a knowledge of modern pathology, tend to remove the traumatic factor in the etiology. There is no doubt in the mind of the writer that the element of trauma in the older statistics is greatly exaggerated; the subject is entirely overestimated, is based upon erroneous pathological basis, and therefore tends to convey an erroneous impression in the

minds of those interested in the subject. In some cases no cause can be assigned but in a large majority of the cases the mother will relate some form of trauma following which her attention was first called to a slight deformity or to some of the symptoms later to be discussed. Whether or not the symptoms existed before the trauma, must remain in doubt in as much as the only history obtainable is that furnished by the mother. It has been shown experimentally that trauma to a joint of a tuberculous animal may cause tuberculous joint disease, but that it will not do so in a healthy animal. It would seem rational to assume, therefore, that slight trauma might aid in lightening up joint diseases in children who inherit a constitutional inability to resist the invasion of the bacillus. It is a matter of frequent observation that children whose family history is exceptionally good become affected with tuberculous joint disease. Nicholas Senn has pointed out that slight trauma such as bruises and sprains are at times etiological factors, whereas, more severe injuries are not nearly so apt to be followed by bone tuberculosis. This fact confirms Bier's theory, that stasis favors tuberculous invasion, while hyperemia is antagonistic to it. The exanthemata must be mentioned as a causative factor in a certain proportion of cases, measles and scarlet fever being the most common eruptive diseases to be followed by these sequelæ. "In short, it is probable that whatever continuously diminishes the power of resistance and repair in growing children, increases the soil for development of the tubercle bacilli and the consequent results."

There is no one symptom or one group of symptoms that can be said to be pathognomic of bone tuberculosis. The symptoms may vary greatly according to the intensity of the infection, the resisting power of the individual and the location of the part affected. One or more of the usual symptom complex may be absent and the symptoms present may simulate various other affections. A unique peculiarity of the symptoms of this disease is the tendency to intermit. The child may complain severely for several days, then have the symptoms gradually disappearing for a time, only to return again with the same degree or possibly a greater degree of severity. Again the child may have a slight limp in the morning, which by noon has disappeared, and again returns the following morning. The length of the intermittency varies greatly. It may be only for a few days or may extend over several months and is even said to be possible to brace an intermittence of years. These lengthy intermittencies can be best explained by the fact that at times the process has been arrested by "walling in," which at some future time has again become an active process and thus produces the return of symptoms.

For simplicity of classification, the symptoms may be divided into two groups: Constitutional symptoms, referrable to the effect of the disease on the general health of the child; local symptoms, those depending upon the certain part affected.

The constitutional symptoms: The mother of a little patient often first notices that the child is not as bright as usual; he may play about as before, but shows signs of fatigue in a short time, desires to rest, to sit still or lie down for short periods from time to time. His appetite gradually fails, he does not crave food like a healthy child. He does not sleep as well as usual, is very restless, and may have night cries during the early hours of sleep. If the weight is taken, it will be found that the child is gradually but constantly losing. The temperature is usually slightly elevated, possibly to the extent of one degree from the normal. In short, the child presents a picture of one who is indisposed. There is a departure from the normal standard of a healthy child, and from these symptoms alone, the physician should be put on his guard and a most careful examination resorted to. The uncertain type of the constitutional manifestations often tends to disarm suspicion and tends to delay in subjecting the patient to a critical analysis.

If any one symptom could be termed most important, most diagnostic, and possibly the earliest, muscular rigidity or spasm most deserves this distinction. Muscular rigidity is usually the first symptom to appear. It is always present to some degree, restricting the joint's normal arc of motion. It is due to a reflex irritability of the muscles controlling the joint which causes them to maintain a condition of tonic spasm of greater or lesser degree. It disappears under full anesthesia, yet it is entirely independent of volition. Increasing stiffness, appearing in the course of treatment, is a sign that either the treatment is inefficient, that there is an increase of the disease, or that rigidity from pathologic destruction of the joint has occurred. The importance of the recognition and accurate study of this symptom cannot be overestimated. It is not only the most important sign of the disease, the chief reliance in the matter of diagnosis, but it is the cause of malformation and deformities. It is responsible for the early limp and the shortening of the limb in hip disease, of the wearing away of the acetabulum and of the head of the femur, of the peculiar gait, the curves and the attitudes assumed in Pott's Disease, and it is also a causative factor in the production of much of the pain. It furnishes the most accurate index of the progress of the case, improving or becoming worse, according to the phase of the disease. The peculiarly diagnostic postures of the individual joints affected with joint tuberculosis are produced not by the disease but by the muscular rigidity that it causes.

Closely associated with muscular rigidity is pain. Unlike muscular spasm, pain is a symptom which is not constant and is a symptom not to be relied upon. As Lovett says, "Pain may be absent at any or all stages of the disease, and is not a diagnostic sign for or against the presence of the disease." When pain is present, it is most commonly referred from the site of the disease, and thus tends in a measure to mislead both parents and physician. In a minority of cases, the pain is referred to the joint itself, but it is most often referred to the peripheral ends of the nerves leading from the parts affected. Thus in hip disease, the pain is usually referred to the distal distribution of the obturator nerve, and is appreciated on the inner surface of the thigh and knee. Many cases of hip disease are treated for weeks with salicylates and liniments for rheumatism of the knee, yet all the classical symptoms of hip disease are present. With the child undressed, a diagnosis should have been made by inspection. A child presenting suspicious symptoms should always be stripped of all clothing before being examined. In tuberculous disease of the spine when pain is present, it is usually referred to the anterior chest, abdomen or limbs. Abdominal pain passes for "stomach ache," thoracic pain for pleurisy, and pains in the limbs for "growing pains"

and rheumatism. In tuberculosis of the shoulder joint the pain when present is referred to the middle of the arm. In sacroiliac disease, the pain follows the sciatic nerve and is often mistaken for sciatica. In knee, ankle, or elbow disease, the pain is often absent entirely, and when present is usually referred to the distal portions of the limb. It may be said here that persistent localized pain in the case of a child is a symptom demanding very great attention.

Analogous to these attacks of pain, are disturbances of the functions of other nerves, manifested in cough, peculiar grunting respiration, dyspnea with cyanosis, gastric disorders, obstinate and recurring vomiting, rectal and vesical disturbances. Patients suffering in this way have often been treated for bronchitis, pneumonia, gastritis, cystitis, and various other affections. Bradford cites a case in which a lateral systotomy was performed for a suspected stone in the bladder. At the operation, no vesical trouble could be discovered, but later at autopsy, disease of the lumbar vertebræ was found.

Tenderness or sensitiveness of the joint, as distinguished from pain, is pain that is provoked by motion or manipulation. Tenderness may be apparent at this early stage. It is more often recognized in those joints that are more exposed than others. Early tenderness is therefore more common in such joints as the knee, elbow, or ankle, and less common in the hip, spine, or shoulder. As long as the contracted muscles hold the joint so as not to permit motion or friction against the inflamed and sensitive areas, the patient may not complain of pain, but motion or manipulation outside of those limits will reveal tenderness.

Night cries, an early and important symptom of this disease, and often the very first symptom to be noticed by the mother, is merely a manifestation of the muscle soreness, that results from the constant tonic spasm to which the muscles have been subjected during the entire day. When the child goes to sleep the contracted muscles, which have been on guard all day, relax. Any sudden movement of the child excites reflex contractions of these muscles controlling the joint, and the sudden contraction gives rise to pain. Muscle soreness is only apparent when the affected muscle is in the state of irritation or motion. The child is rarely awakened by the pain, but usually moans or cries and remains sleeping. If awakened, it makes no complaint of pain and the cry is supposed to be caused by a "bad dream." Night cries are most common during the early hours of sleep when muscular relaxation is most complete. They may occur many times during the night, but do not occur if the child is awake.

Atrophy of the muscles in the neighborhood of the joint is another early symptom of importance. It begins sharply and very early. It was previously supposed to be reflex to the disease of the joint, but more recent investigations indicate that it is an atrophy not of disuse but rather of the type of excessive use; the muscles being in a state of constant tonic spasm during the day with less than the normal blood supply, thus less nutriment and also a defective inervation.

A difference in contour, a filling out of the normal depressions, and an apparent enlargement of the joint can also be noted at this early period. It is entirely independent of any distension of the joint with fluid, and is therefore most evident in those joints most exposed.

It is unnecessary here to discuss such symptoms as shortening of a limb, ankylosis, abscess, discharging sinuses or late deformities which make up clinical pictures easily recognized on sight. A diagnosis should have been made long before these are present.

Before leaving the subject, however, it would be well to mention a few of the more important laboratory methods of diagnosis.

Radiography is of very great value and should be used in all doubtful cases. The slightest bone erosion can be determined and interpreted by a skillful radiologist and even before erosion, the radiogram will indicate, by the diminished resistance to the passage of the *x*-ray, the greater vascularity of the epiphyses, which always is present at this early stage.

Time would hardly permit a discussion of all of the laboratory methods available, especially with reference to the various forms of sera, tuberculin tests, and the opsonic index. The subject, however, would not be complete without mention of the most recent investigations of Dr. Randle C. Rosenberger. Dr. Rosenberger by means of his own special technique has been able to demonstrate in the peripheral circulation the presence of the bacillus of tuberculosis in every case of phthisis, also in those cases in which the joints were the parts affected. Moreover, Dr. Rosenberger claims that the tubercle bacilli are present in the blood stream in the most incipient cases, even before physical signs have become manifest. This being the case, Dr. Rosenberger's revelations should be of enormous value to orthopedic surgery and undoubtedly will, in the future, be instrumental in establishing diagnosis that heretofore would not have been possible.

200 South Twelfth Street.

THE REPORT OF A PECULIAR CASE OF MENINGITIS IN WHICH TREATMENT BY ANTIMENINGOCOCCIC SERUM WAS ATTEMPTED.

By JOHN PATERSON GARDINER, M.D.,

TOLEDO, OHIO.

PATHOLOGIST TO THE TOLEDO HOSPITAL.

The use of the antimeningococcic serum in the treatment of epidemic cerebrospinal meningitis is of such recent date that exhaustive reports have not yet been made, but such satisfying results have already been obtained in reducing the mortality percentage that its general employment is now assured.

There have been four cycles of epidemic meningitis occurring in America and Europe during the nineteenth century. The first cycle began in Geneva, Switzerland, in 1805, gradually spreading through Europe and the United States, and ending about 1828. According to Hirsch in his Geographical and Historical Pathology, we are now in what might be called the fifth cycle, beginning with the localized outbreaks in various sections of Europe and the United States in the early '90s and continuing in sporadic form in all America's large cities. The epidemic has reached alarming proportions at times, the number of deaths from this disease alone in New York City ran for a period of weeks in 1904 at more than 100 each week.

The causative agent of this disease has been known since 1887, when Weichselbaum described a diplococcus occurring both within and without the leucocytes in the spinal fluid in this disease, and reported the findings in six cases. The mortality

.n cerebrospinal fever varies with the different epidemics. The usual death rate with the ordinary methods of treatment runs from 60 to 80 per cent. In 1906, Dr. Flexner reported the result of the employment of an antimeningococcic serum upon the course of a small number of cases of epidemic meningitis. This serum he prepared by inoculating the horse, first with gradually increasing doses of dead meningococci, then of living cocci, and finally of an autolysate. The effect of the serum in man is due, according to Flexner, partly to an antitoxic action, partly to the stimulus that the serum gives to increased phagocytic digestion, and partly to its direct injurious action upon the cocci. The results were so satisfactory that the employment of the serum on a wider scale seemed called for. Recently he has reported an analysis of 400 cases of epidemic meningitis in which the serum was used.

The cases upon which he bases his results, have been taken from widely separated parts of the United States, Canada, and Great Britain, sometimes from cases occuring in small epidemics, like that in Akron, Ohio, sometimes, in sporadic outbreaks of considerable extent, as in Belfast, Ireland, and Edinburgh, Scotland, and also in Boston, Baltimore, Cincinnati, and Philadelphia.

In each instance, in which the serum has been supplied, Dr. Flexner has required that a bacteriological diagnosis be made, and in doubtful instances the slides have been examined at the Rockefeller Institute and even cultures prepared from the exudate, so his conclusions on the result of the employment of the serum are authoritative.

In making the figures upon which his tabulation is based, account was taken of the ages of the patients, the period of the disease at which the serum was first injected, the effect upon the temperature, the objective and subjective symptoms, the number and viability of the diplococci in the spinal exudate, the duration of the fever and other symptoms. In one way only was any selection of cases made, namely, that all cases in which death occurred within twenty-four hours after the first dose of serum were excluded from the tabulation. The total number of cases subjected to analysis was 393. The total number of recoveries was 295, and the total number of deaths was 98, giving 75 per cent. recoveries and 25 per cent. deaths, practically reversing the mortality rate under other methods of treatment. According to the ages of the patients the table is as follows:

Age.	Number of cases.	Recovered.	Died.	Mortality, Percentage.
Under one year.....	22	11	11	50
One to two years.....	19	11	8	42
Two to five years.....	68	52	16	23.5
Five to ten years.....	79	70	9	11.4
Ten to twenty years...	105	80	25	23.8
Over twenty years....	87	64	23	26.4
Not given.....	13	7	6	46.1

The table, analyzing the time of injections, shows the undoubted beneficial results of early injection.

Period of injection of serum.	Number of cases.	Recovered.	Died.	Mortality, Percentage.
One to three days.....	123	107	16	16.5
Four to seven days....	126	96	30	23.8
Later than 7th day....	112	73	39	35

Flexner says, whether there is complete anatomical restitution of the meninges in these cases can be determined only by post-mortem examination, but that complete functional restoration can take place may be regarded as an established fact.

Under the influence of the serum injected, the spinal exudate rapidly looses its turbidity, there is a decrease, often very rapid, in the number of the leucocytes of the blood, the diplococci are reduced in number, disappear from the fluid part of the exudate, to become wholly intracellular, swelling and fragmentation is noticed, and they stain diffusely, and indistinctly, and lose viability in culture.

The clinical effects of the serum are a fall in temperature, a marked improvement in the patient's general condition, a cutting short the course of the disease. In regard to the permanent sequelæ, with very few exceptions recovery is complete. The complications of a serious character arising during and as the result of the meningeal inflammation, in the series reported are, deafness, seven times, blindness and deafness once. Most of these were noticed before the injections were begun. In Flexner's series nineteen relapses occurred, in which fourteen patients finally recovered and five died. Early recognition of the recurrence and prompt and vigorous resumption of the injections will arrest the progress of the disease. The duration of the active symptoms, after the employment of the serum, varies. In Flexner's analysis eleven days was the average; in many, however, active symptoms ceased sooner, and in some they disappeared in one or two days after the administration of the serum. Dunn of Boston and Ladd of Cleveland, who have been studying the effect of the serum, reach practically the same conclusion as does Flexner. Wassermann has been doing the same pioneer work in Europe as Flexner has in America.

The following is a case of sporadic cerebrospinal meningitis (probably epidemic) for which Dr. Flexner sent me his antimeningococcic serum:

Iona M., female, age 20 months. I saw the child the night of September 22, 1908. The mother told me at that time that the baby had been sick about a week with diarrhea and that a diagnosis of typhoid fever had been made. Her condition was as follows: Pulse 140, temperature 103.2°, respiration 54; extremely restless; no eruption on the body; the right lung consolidated, as also a portion of the left lower lobe posteriorly. There were from seven to ten movements a day; these were dark green and had a very foul odor. The urine was voided with the movements. The child was able to take some nourishment. A diagnosis of lobar pneumonia complicated with gastroenteritis was made. After October 6 all symptoms gradually subsided, the consolidation disappeared, but the pulse remained noticeably full, 120. The movements, reduced to three or four a day, were yellow, streaked with green and contained milk curds. The child appeared to be convalescing. The morning of the twelfth, the subcutaneous tissue of the lower eyelids, the abdomen, the inner aspect of the thighs, back of the hands, the ankles, and the dorsa of the feet, was edematous. Urine examination, specific gravity 1.016, light amber color, acid reaction, no albumin, and only a few epithelial cells. The enteritis returned and was as severe as ever. By October 17 the edema had disappeared, the diarrhea continued, not yielding to treatment, and the child gradually lost strength.

On October 19 the posterior muscles of the neck were noticed to be in a state of tonic spasm. Meningitis was evident, but whether it was postpneumonic or a sporadic form of cerebrospinal, was a question. On further detailed questioning of the parents and also the grandparents the following

fact was learned from the grandfather who was with the baby when it was taken sick. The child was seized with an attack of vomiting and went into a spasm. The diarrhea set in the next day. Previously the child had been in its usual health, though never vigorous.

On October 20 the child was not able to communicate its want with its usual intelligence. It developed internal strabismus of the left eye and nystagmus of both eyes, this latter symptom continued through the course of the disease. The tonic spasm of the neck muscles increased and the movements of the body had a tendency to remain fixed. A lumbar puncture was made, drawing off 15 c.c. of slightly turbid fluid. Examination showed few cells and no microorganisms. It was noticed that while the fluid was being withdrawn the child developed purposeless movements of the arms and legs and a contraction of the masseter muscles, producing a grating of the teeth, alternating with a protrusion of the tongue, about sixty times a minute. This condition lasted from two to three hours after the puncture. The child seemed a little better on the 21st, but worse again on the 22d, when lumbar puncture was performed again and only 10 c.c. of slightly turbid fluid could be recovered; a centrifugalized specimen revealed a gram-negative diplococcus which showed a tendency to form tetrads. I prepared slides and sent them to Dr. Simon Flexner. His comment on the slides is as follows: "The slides which you have sent contain a surprisingly large number of biscuit-shaped diplococci, sometimes arranged in tetrads, and while I cannot, of course, make a positive statement, I think it likely, in view of the fact that they are obtained from the cerebrospinal fluid, that they are the *Diplococcus intracellularis*. What is surprising is that they should be entirely extracellular."

In the meantime, the child rapidly lost ground, becoming emaciated, almost in a night. On the 26th, another puncture was made, but no fluid was obtained. On the night of the 27th, the serum having been received, another lumbar puncture was attempted, but no fluid could be withdrawn. A prolonged effort was made to introduce the serum into the canal but it was of no avail. A new site was chosen between the second and third lumbar vertebræ, instead of between the third and fourth, where all former punctures had been made, but still no fluid could be obtained nor could the serum be injected. Having in mind a case mentioned by Ladd, in which the patient recovered when the serum was injected subcutaneously, I therefore, as a last resort, injected 15 c.c. into the back subcutaneously, though Dr. Flexner does not indorse any method other than injection of the serum into the cerebrospinal canal. Six hours after the injection of the serum the child died. An autopsy of the head is obtained. As the calvarium is removed there is a sudden gush of fluid from the right occipital lobe of the brain, which comes out with such force that it enlarges an abrasion made by the saw, to a rent 6 cm. in length. The whole right hemisphere shrinks. On inserting the finger through the opening, the contour of the lateral ventricles is made out, showing this to be an internal hydrocephalus. Approximately 200 c.c. of fluid escapes. The meninges are congested. The base of the brain and the spinal cord as far down as can be seen are covered with a thick purulent exudate. The portion of the brain lying between the skull and the lateral ventricles, surrounding the seat of rupture, is thin, caused by the pressure of the fluid. On the floor of all the ventricles there is a thick purulent exudate like that found externally at the base of the brain. The fourth ventricle is entirely filled, cutting off all possible interchange of fluid between the spinal canal and the ventricles. Smears from the pus show intracellular and extracellular diplococci. Cultures are made on glycerin agar from the cerebrospinal fluid of the lumbar puncture and from the cerebrospinal fluid obtained at the autopsy; these are negative.

This case illustrates some of the fatal complications that may arise to render useless the employment of the serum, according to the usual method of administration. There may come a time in meningitis when no more fluid can be withdrawn from the spinal canal, nor can any fluid be injected into the canal, because of the dense exudate present. Another complication, which is liable to develop at any time, is obstructive hydrocephalus, and as the cerebral exudate increases in amount, fatal pressure ensues. For the relief of these conditions several operations have been suggested. Laminectomy has been performed to secure better drainage from the spinal canal, but this may fail because the canal may become closed by the exudate. Suboccipital drainage has been attempted, which, though better, has not proven entirely satisfactory, for the reason that the obstruction may form higher up. The most recent effort to overcome these difficulties has been to puncture the lateral ventricle and draw off the fluid, and, still more recently, to injecct antimeningococcus serum directly into the ventricles.

Cushing and Sladen have described, in *Experimental Medicine* for October, 1908, a series of cases in which this attempt was made. They found that in the infant the ventricles may be safely entered through the outer angle of the fontanelle, at a point about 2.5 cm. from the median line. In the adult, on the other hand, cranial penetration is necessary, and in most of their cases Kocher's point of election has been chosen. There is no especial difficulty in the procedure. A small patch is shaved, and a short, one-inch linear incision made 3.5 cm. from the mid-longitudinal line, about 5 cm. anterior to the sulcus centrallis. The bone is exposed and penetrated by a Doyen perforator, followed by a burr, which leaves a cup-shaped fossa and gives sufficient exposure of the dura to assure the operator that there is no large underlying cortical vessel. The hollow exploratory needle, which should have a blunt point with the openings on the side, is then gently inserted into the second frontal convolution, perpendicular to its surface and at a depth from 4 to 5 cm. This readily finds the ventricle.

Cushing and Sladen believe that the fatalities in many of the cases of cerebrospinal meningitis have occurred from cerebral pressure, rather than as a result of an overwhelming intoxication or terminal infection. Under serum treatment the formation of a fibrinoplastic exudate is less marked than in cases treated by other means, therefore lessening the chance of obstruction.

Flexner issues a word of warning that care should be taken not to inject more serum into the ventricles than is withdrawn, because pressure symptoms are much more serious here than in the spinal canal.

When other methods fail, then, as in the case reported, the operation of choice would be ventricular puncture with injection of the antimeningococcic serum.

THE TRANSMISSIBILITY OF HUMAN CARCINOMA TO ANIMALS.

ONE of the arguments of those who deny the infective nature of cancer is that all attempts to inoculate the lower animals with the neoplasm have been negative in their results. This really proves nothing, however, any more than a failure to inoculate a dog with estivoautumnal fever would disprove the existence of the pathogenic protozoan. A successful experiment of the kind would, on the other hand, provided all sources of fallacy could be excluded, have considerable significance; and evidence of this nature is apparently not wanting. Gaylord, it is true, says that "it can be generally stated that human cancer is not transmissible to animals by direct inoculation," and also that "it must be conceded that cancer is not directly communicable by contact from human beings to animals, or from animals to human beings;" nevertheless he says that "in two instances animals which were inoculated with human cancer developed neoplasms under conditions which make it possible that the growths were due to the inoculation." Mayet and others have also reported a few cases of apparently successful inoculation of human carcinoma into mice and other animals, but most experiments of this nature have been failures, and even the seemingly positive results are not above suspicion.

In the *Lancet* of June 5, 1909, Mr. Ford Robertson suggests that the cause of failure in most of these inoculation experiments may have been that the methods employed were not suitable. The protozoan organisms, if such there be, may have to be introduced in large numbers, owing to their great vulnerability, or they may have to be introduced during a particular phase of their life cycle. He accordingly conducted a series of experiments with this idea in mind, introducing the cancerous material subcutaneously and per os, in large doses, and after various periods of incubation. His experiments were made on mice with fluid from the peritoneal cavity in a case of malignant peritonitis and with the pleural exudate from a patient suffering from malignant pleurisy secondary to mammary carcinoma. In the first series of experiments six mice received injections in the abdominal wall of one cubic centimeter each of the peritoneal fluid, incubated for about two months. The results were negative. In the second series five mice were fed with an equal amount of the same peritoneal fluid. The results of this experiment were also negative. The experiments with the pleural fluid were, however, more successful. In this series thirty mice of ages varying from three to twelve months were fed with 20 c.c. of this fluid which had been incubated at blood heat for seven weeks, and the following day they were fed with a like amount of the peritoneal exudate incubated for nine weeks. In the course of the subsequent five to fourteen months seven of these mice developed carcinomatous tumors, three of which appeared in the mammary gland, two in the lung, one in the testicle, and one in the uterus. In two other cases there were fatal lesions in the stomach and liver which were apparently, though not certainly, cancerous. Another mouse, one of thirteen born in the cages during the course of the experiment, developed a tumor of the mammary gland which had the histological character of an adenocarcinoma. None of the controls in any of the experiments developed any neoplasm, so Robertson concludes that the growth of the tumor in these seven animals was determined by some agent contained in the carcinomatous material on which they were fed. That this growth was determined by a living virus and not by a chemical substance was, the author thinks, shown by the result of several cultures on non-nutrient agar-gelatin made from the mammary tumor in one of these mice, in which were demonstrated certain morphologically characteristic forms identical with those previously observed in malignant tumors from the human subject and in one of the original Jensen mouse tumors.

Robertson is frankly a partisan of the parasitic theory of cancerous growth, and asserts as his belief, based on this and other observations, that "a group of protozoan organisms, to be classed among the mycetozoa and including very numerous pathogenic species, is associated with tumor growth, just as very numerous pathogenic species of schizomycetes are associated with inflammation. The main phases in a complicated life cycle have now been demonstrated in sections of tumors, in sections of agar cultures from tumors, and in films of the centrifuge deposit from fluid from cases of malignant pleurisy secondary to carcinoma of the breast. The phases recognized include forms with flagella, sporoblasts and their residua, nucleated forms, some of which have been observed in mitosis, and certain other remarkable bodies of characteristic appearance which almost certainly represent gametes."

It is not likely that the results of the few experiments detailed in the paper from which we have quoted will be accepted as conclusive by the opponents of the contagion theory, and even those who have no theories, but are still looking for light, will hardly have their doubts set at rest by them. Nevertheless, one positive result, in experiments of this nature, weighs against many negative ones, and as these results multiply, if the investigators are able to exclude the many factors which may be alleged as vitiating their experiments, the noncontagionists will find it harder to support their position. To the unprejudiced observer it seems as

though the supporters of the parasitic theory were slowly gaining ground, but they have a good deal of hard work yet to do before they can definitely establish their position. One can only wish that they may succeed, for it is this theory that holds out the greatest hope of the final triumph of therapy over this most formidable, because most mysterious, foe of mankind.

RATIONAL FEEDING IN THE VOMITING OF INFANTS.

The subject of the feeding of infants, especially that part of it which deals with the use of barley water, lime water, and sodium citrate, the so-called milk modifiers, is at present based largely on empiricism. Each physician has his own opinion as to the efficacy of one or other of these various substances, but he rarely is able to tell why he prefers any one especial modifier, and when he meets with a persistent case of vomiting he usually tries each one in turn until he obtains a mixture which seems suitable to the particular case. This is not only distinctly worrying to the physician but is decidedly harmful to the small patient, who has to wait until a proper diet is reached in this time-consuming, haphazard manner.

That an effort is being made to rectify this fault and to put this part of infant feeding on a more rational footing is shown by an article by T. Wood Clarke in the June number of *The American Journal of the Medical Sciences*. Clarke, working at the Babies' Hospital and the Rockefeller Institute in New York, reports a long series of experiments by which he endeavored not only to learn the exact chemical action of these modifiers in the healthy infant's stomach, but also sought to discover whether there was any abnormality in the gastric secretion in cases of marasmus and chronic vomiting. In some of his findings the author agrees with the accepted ideas, while in others he differs markedly. He finds that the motility of the stomach varies inversely to the concentration of the fool, and that, therefore, the more dilute the milk the more frequently the child may be fed. Lime water, instead of acting to reduce the acidity of the stomach, as is commonly believed, actually stimulates a further secretion of acid, enough at times to produce a relative hyperchlorhydria. Sodium citrate, on the other hand, neutralizes the hydrochloric acid without causing any further secretion. Barley water seems to have no constant effect on gastric secretion. A further finding is that the chronic vomiting may be divided into two classes, associated respectively with hypoacidity and hyperacidity. These give no outward symptoms to distinguish them from each other and can be differentiated only by a test feeding. The removal of a test feeding from an infant is a simple and harmless procedure; it could well be done in all cases of persistent vomiting in infancy, and might possibly give information which would aid in the rational treatment of these troublesome patients. The author describes the apparatus he has devised for removal of the stomach contents and discusses the best form of test feeding.

Whether this work, carried out in a laboratory, and as yet not utilized to any extent in the actual therapeutic handling of ill infants, will be of practical value is difficult to say. The use of the test feeding on the infant and the modifying of the food to meet the requirements of the abnormal gastric juice will not in all probability prove a panacea for infant indigestion. It is, however, an earnest and conscientious effort to attack the problem of infant feeding in a rational manner, to remove the use of the milk modifiers from the realm of guesswork, and to place it on a more scientific foundation.

THE MODE OF INFECTION OF EPIDEMIC CEREBROSPINAL MENINGITIS.

As the ever growing and ever more favorable reports continue to appear, not only from all parts of this country, but from Great Britain and France as well, demonstrating the value of the serum treatment of epidemic cerebrospinal meningitis, one is tempted to believe that this disease has at last been conquered. Nevertheless, in spite of justifiable enthusiasm, it must be remembered that an infectious disease, with a mortality of over twenty-five per cent., is a matter of serious import, even if the mortality has been reduced in a few years from eighty per cent., and complacent satisfaction over what has been done should not be allowed to interfere with further efforts to conquer the disease. The work of Flexner and Jobling has been of great value, and these investigators have accomplished what they attempted, the discovery of a curative serum. But with full appreciation of their success, no remedy, however specific it may be, can ever stamp out a contagious disease, especially one so acute and rapid in its course as epidemic cerebrospinal meningitis. Patients have infected others and often have died before the serum could be administered.

The only sure method of controlling any infectious disease is the development of an effective system of prophylaxis. In order to accomplish this, though a knowledge of the cause of the disease is an aid, it is not so necessary as a thorough acquaintance with its mode of transmision, a fact well illustrated in the case of yellow fever. In cerebrospinal meningitis the infecting organism described by Weichselbaum in 1887, and associated with the epidemic form of the disease by Jaeger in 1895, has been carefully studied and is an easily recognized germ. For years, however, its mode of transmission from man to man has been a mystery. That much has been done in recent years on this subject is shown by the voluminous report by Elser and Huntoon, in the June number of the *Journal of Medical Research*. In speaking of the contagiousness of the disease, they state their belief that it is carried by direct transmission only and cite the extreme vulnerability of the specific micrococcus as a reason for this opinion. The organism, while growing fairly well if properly cultivated, dies in a few hours if allowed to dry, a fact which makes transmission by dust unlikely. The theory of contagion by micrococcus "carriers" is strongly emphasized,

as in the recent New York epidemic, the specific organism was found in the nose and throat not only in the patients, but also in a large proportion of those who had come in contact with them, although they themselves remained quite well. These persons were probably not susceptible to the disease but were able to convey it to those who were. The contagion takes place through the respiratory tract, and thence the organisms find their way to the meninges through the blood. It is extremely difficult to remove the micrococci from the nose and throat of the "carriers," and in spite of rigid local treatment, the organisms remain for long periods. In the acutely ill they are found in the throat early in the disease, but usually disappear after from five to ten days.

Such are the facts elicited by this careful research regarding the mode of contagion of epidemic cerebrospinal meningitis, but the authors offer no suggestions as to prophylaxis. This was not their problem. It now remains for the sanitarians to apply these facts to hygienic and social conditions and to devise practical means for protection against the disease.

Atoxyl Amblyopia.

In recent years a new arsenic compound, arsenic-acid anilide or atoxyl, has been brought to the attention of the medical profession as a remedy for the sleeping sickness and for syphilis. As so often happens when a new drug is introduced, its advantages first attracted attention and it was only after a more extended trial that the untoward efforts became manifest. Among the injurious effects of this drug which have been recently observed is a peculiar form of blindness. In the *Berliner klinische Wochenschrift* for May 31, 1909, Paderstein reports two cases of atoxyl amblyopia and collects the cases in the literature. The symptom complex is fairly uniform. The condition begins usually after the drug has been taken for several weeks, and starts with some impairment of visual acuity, with a marked narrowing of the visual field, especially on the nasal side, going on to complete scotoma. According to the severity of the attack, which is in no way proportioned to the amount of the drug taken, a central scotoma develops. The ophthalmoscopic findings may at first be normal, or there may be a narrowing of the retinal arteries, and a blanching of the papilla, which in the worst cases may become a definite optic atrophy. The disease is always bilateral. There are various theories as to the cause of these changes, some thinking that the disease is primary in the optic nerve, others that it is due to a lesion of the retinal vessels, and still others that it begins in the retinal ganglion cells. Nonne, at autopsy, found degeneration of the optic nerve in its entire cross section, and of the central bundle of the chiasm, while the cuneus was normal. On the other hand Igersheimer in experimental work on cats, by injection of the drug into the eye in minute dose found beginning degeneration of the ganglion cells and nerves of the retina. Whatever may be the pathology of the condition, the important point is that this drug in certain cases may produce an affection of the eyes, which may be but a dimming of a part of the visual field, or may result in total blindness.

Scarlet-Red in the Treatment of Chronic Ulcers.

That much is to be desired in our treatment of chronic ulcers is only too apparent from their slow healing in many cases despite the most painstaking attention to the dressings and other details of their treatment. The sluggish indolent ulcers frequently drag along for years without improvement, complicated unfortunately by the fact that so many of the patients cannot afford to take the rest cure. In 1906 Fischer discovered that a solution of scarlet-red (an anilin dye which is the sodium salt of one of the derivatives of disulphonic acid) in olive oil injected subcutaneously caused an inflammatory reaction, with a proliferation of only the germinal layers of the skin, and two years later Kaehler, noting this peculiarity, turned it to account in the treatment of ulcers. In the *Johns Hopkins Hospital Bulletin* for June, 1909, John Staige Davis presents an optimistic report of sixty cases treated by him with scarlet-red. His cases were not selected, many of the ulcers being in bad condition when he began treatment. Many of the patients remained at their daily work. Davis prepares the U. S. P. ointments —boric, zinc, iodoform, etc.—with a simple vaseline base and with from two to twenty per cent. of scarlet-red thoroughly mixed in. He finds the eight per cent. mixture the best for the average case, though the strength must be determined by carefully watching the effect of the treatment. The granulations are first brought into proper condition by cleansing with boric acid, the excess being kept down with silver nitrate applications. If the ulcer is small the whole of it is covered with the scarlet-red, but if it is large only the edges are treated while the rest is left bare or a bland ointment is applied. The scarlet-red dressing should alternate every twenty-four or forty-eight hours with some bland ointment. In some of the cases in which there had been no improvement for months with the ordinary ointments the ulcers began to improve immediately on the application of scarlet-red and rapidly healed over. Large luetic ulcers, which had resisted local and constitutional treatment for from three months to five years, healed promptly under this treatment. Scarlet-red in mercurial ointment is especially useful in these cases. If too strong a mixture is applied there is danger of inflammation and eight of Davis' cases were not benefited on account of the severe irritation produced. He recommends the use of scarlet-red also to stimulate the growth of skin grafts.

News of the Week.

A Less Murderous Fourth.—The Independence Day celebration this year was much more quiet and freer from casualties than any Fourth of July for many years, and this in spite of the fact that it was observed on two days. The returns on Tuesday morning showed only sixty-one deaths, eleven less than last year, and 3,246 more or less serious injuries. The cases of tetanus resulting from these will, it is hoped, be fewer owing to the more general employment of tetanus antitoxin as a prophylactic.

Alleged Leper in New York.—Early, the man who was quarantined for nearly a year by the Health Commissioner of Washington because he was suspected of being a leper, has at last been freed and is now in this city. It is said at the New

York Skin and Cancer Hospital that he has no symptoms of leprosy. He was brought to New York in a baggage car.

Health of New York City.—Commissioner Darlington has issued a semi-annual report covering the mortality statistics for the first six months of 1909 as compared with 1904. The total death rate has dropped from 22.08 to 16.92. The mortality from typhoid fever from 1.09 to 0.74, malaria from 0.24 to 0.08, measles from 3.73 to 3.14, scarlet fever from 3.36 to 2.42, diphtheria from 6.64 to 4.74, grip from 2.18 to 1.18, pulmonary tuberculosis from 23.83 to 20.50, cerebrospinal meningitis from 4.19 to 0.72, lobar pneumonia from 28.97 to 14.24, nephritis from 17.20 to 13.03, and old age from 2.92 to 1.40. The mortality from heart disease has increased from 13.74 to 16.24, and of whooping cough from 0.53 to 0.78. That the improvement in the city's health has been steady and progressive is shown by the comparison of the total mortality rates for the first six months of the past six years: 1904, 22.08; 1905, 19.04; 1906, 18.88; 1907, 18.99; 1908, 17.59; 1909, 16.92.

Typhoid Epidemic Probably Due to Flies.—Over forty cases of typhoid fever have occurred in Washburn's brickyard in the town of Ulster, N. Y. The water has been pronounced pure by the State Bacteriologist at Albany after bacteriological analysis. The State board is of the opinion that the epidemic can be traced to flies or mosquitos. The well from which the water was taken is 80 feet deep in solid rock. The State Department has also recommended that the patients be isolated from flies or mosquitos while sick or convalescent, and this will be done with the forty-six patients remaining in the town. Nets have been provided in the houses in the vicinity to keep out flies and mosquitos which might transmit the disease germs to other people.

La Guayra Free of Plague.—The American Consul at Willemstad, on the Island of Curacoa, reported to the State Department last week that the city of La Guayra on the coast of Venezuela, which has been infected with plague for more than a year, is now free from this disease. A bounty has been offered by the Government of 4 cents for every rat and 1 cent for each mouse. During last year about 9,000 rats and 60,000 mice were killed.

Popular Education in Sanitary Affairs.—The States of Louisiana and Kansas are planning widespread education of the masses in matters of public health and hygiene. Dr. Harvey Dillon, President of the Louisiana State Board of Health, will visit personally each parish in the State and deliver speeches on public health questions. For the next two years Kansas will spend $10,000 a year for the education of its people in matters of sanitation and hygiene. The work will be in charge of Dr. S. C. Emley of the medical faculty of the University of Kansas, under the direction of the State Board of Health.

Milk Contest Extended.—To allow the high school and college students in the various States from which New York gets its milk supply a chance to compete for the prize which James Speyer and Archer M. Huntington have agreed to give through the Health Department for the best composition on the subject of sanitary milk production and delivery to market, Health Commissioner Darlington has decided to extend the time limit for the compositions to be sent in until October 15.

Junior Sea Breeze, the Rockefeller summer hospital for babies at Sixty-fourth street and the East River, managed by the New York Association for Improving the Condition of the Poor, was opened July 2. Four district nurses are visiting poor homes in the section about Junior Sea Breeze and will refer sick babies to the Rockefeller institution whenever necessary. A feature of the work which will begin soon will be the daily conference for mothers at which the nurses will instruct the mothers in the proper care of their babies.

The Floating Hospital of the St. John's Guild in New York has opened for the care of sick infants. On Tuesdays and Fridays the hospital boat sails from the North River, touching at West Fiftieth, West Thirty-fourth, and West Tenth streets. On Mondays and Thursdays from East Twenty-fourth, East Third, and Market streets. On Wednesdays and Saturdays it starts from Brooklyn, the landings being at North Second street, Hudson Avenue, and Hamilton Avenue. Tickets may be obtained at the Department of Health, the hospitals, day nurseries, and at many of the churches.

New Tuberculosis Hospital.—The Brooklyn Central Labor Union has obtained permission from the State Board of Health and the local Health Officer to erect a hospital for tuberculosis near Medford, Long Island. The hospital is to be built on a tract of 65 acres, will contain 100 rooms, and cost $50,000.

University of Tennessee Medical School.—The medical and dental departments of the University of Tennessee located at Nashville will hereafter be conducted from Knoxville and entirely under the direction of the president of the University of Tennessee, Dr. Brown Ayres, and the trustees of the institution. Decided changes are planned in regard to the future management of the institution. For a number of years, the departments have been conducted from Nashville, and the fact that it is a State institution and that it is an integral part of the great State university was not appreciated or made patent. The equipment at the department was owned by the members of the faculty. The members have donated all this property to the State institution and the faculty will be reorganized. Dr. R. O. Tucker was appointed Dean and Dr. B. D. Blake, for years a member of the faculty, was made Bursar and Professor of Materia Medica. The foregoing with Dr. William D. Haggard will investigate the situation at Nashville and will make recommendations as to the new faculty. It will then be named.

Research Laboratory for College of Physicians and Surgeons.—Plans have been filed by Columbia University for a laboratory for private physiological research to be erected on the roof of the north wing of the College of Physicians and Surgeons on West Sixtieth Street. It is to be floored with reinforced concrete and will contain a dozen rooms for the various branches of laboratory work with two corridors and two rooms for operating experiments.

Charitable Bequests.—By the will of the late William J. McAllister of Philadelphia, the sum of $3,000 is devised to the Presbyterian Hospital, while realty holdings to the valuation of $5,300 are to revert to the hospital on the death of a sister for a free bed to be named for the testator.

By the will of Harry Samuel Henry, his entire

estate, estimated to be worth $1,500,000, is to be divided eventually among five Philadelphia hospitals. The income from the estate is to go to the widow and two sisters for life. Upon the death of the three women the estate is to be divided equally among the University, Episcopal, Children's, Presbyterian and the Pennsylvania hospitals.

Gift to McGill.—Lord Strathcona, the Canadian High Commissioner in London, has given to McGill $500,000. Of this amount $450,000 is to be used in completing the new medical building and $50,000 in augmenting professors' salaries.

Memorial to Dr. McCosh.—The auxiliary yawl, *Andrew J. McCosh*, a memorial by Princeton men to the late Dr. Andrew J. McCosh of New York, has started on her long voyage to the Labrador Coast. She will make that voyage under a crew of Princeton graduates, mainly recruited from the class just graduated. Dr. McCosh was a great admirer of Dr. Wilfred T. Grenfell, whose medical work along the barren Labrador Coast has so often excited the admiration of young college men. So, when the question of a memorial to him came up, Princetonians, graduates and undergraduates, took the presentation of a yawl named for him, designed to further the work of Dr. Grenfell, as the most appropriate memorial that could be hit upon. Princeton men of all ages subscribed.

Honorary Degrees.—Harvard University on June 30 conferred the degree of Doctor of Medicine *honoris causa* on President-emeritus Charles William Eliot of Harvard University. In conferring upon Dr. Eliot the degree President Lowell said: "It has not been our custom to confer the degree of Doctor of Medicine, *honoris causa*, but an exception is fitting in the case of one who—in the opinion of professors of medicine—has accomplished more for the progress of medical education in this country than any other living man, Charles William Eliot. Not in its buildings alone, but also in the instruction and research within its walls, he found our medical school brick and left it marble." The degree of Master of Arts was also conferred upon Dr. Wilfred T. Grenfell of Labrador.

Yale University on June 30 conferred the degree of Master of Arts upon Dr. Joseph A. Blake of New York and Dr. John P. C. Foster of New Haven.

Appointments.—Dr. W. H. Snow of the Leland Stanford University has been appointed a member of the California State Board of Health.

Dr. Wilbur Tileston of the Harvard Medical School has been elected Assistant Professor of Medicine in the Yale Medical School.

Dr. E. B. Parsons of Palestine, Texas, has been appointed a member of the Texas State Board of Health, vice Dr. H. E. Whiteside, who has resigned on account of ill health.

Dr. Myles Standish of Dartmouth College has been appointed Williams Professor of Ophthalmology; Dr. Otto E. Folin Professor of Biological Chemistry, and Dr. Elmer Ernest Southard, Bullard Professor of Neuropathology in the Harvard Medical School.

Dr. Charles H. Knight has resigned the Clinical Professorship of Laryngology in the Cornell University Medical College and Dr. James E. Newcomb, formerly Clinical Instructor and Chief of Clinic, has been appointed to succeed him with the rank of Assistant Professor.

Dr. C. H. Wheeler has been appointed Health Officer of Portland, Oregon.

Dr. W. L. Richardson of Boston, former Dean of the Harvard Medical School, has been elected one of the Overseers of Harvard University.

The Medical Society of Northern Virginia.—At a meeting of this society on June 24 the following officers were elected: *President*, Dr. Stephen Harnsberger of Catlett, Fauquier County; *Secretary and Treasurer*, Dr. Charles A. White of Washington, D. C. The next meeting will be held at Washington, D. C., in November.

The Manitoba Medical Association met at Brandon, Man., on June 23 and elected the following officers: *President*, Dr. Harvey Smith of Winnipeg; *Vice-presidents*, Dr. Hicks of Griswold and Dr. J. Matheson of Brandon; *Honorary Secretary*, Dr. J. Halpenny of Winnipeg; *Honorary Treasurer*, Dr. Rorke of Winnipeg; *Executive Committee*, Dr. Wright of Oak Lake, Dr. Keele of Portage la Prairie, Dr. Ross of Selkirk, Dr. Speeckles of Pilot Mount, and Dr. Harrington of Dauphin.

The Medical Association of the Pacific Northwest will hold its first meeting at Seattle, Washington, July 20-23, 1909. The association comprises the British Columbia Medical Association and the Washington, Idaho, and Oregon State Medical Associations.

The Lake Keuka Medical and Surgical Association will hold its tenth annual meeting at Grove Spring, Lake Keuka, New York, on July 15 and 16, 1909. The *President* of the association is Dr. O. J. Hallenbeck of Canandaigua and the *Secretary and Treasurer* Dr. H. B. Nichols of Pulteney.

The American Institute of Homeopathy, meeting in Detroit June 22-24, elected the following officers: *President*, Dr. James W. Ward of San Francisco; *Treasurer*, Dr. T. Franklin Smith of New York; *Secretary*, Dr. Richey Horner of Cleveland; *Censor*, Dr. J. B. Garrison of New York.

The Iowa Union Medical Society, meeting at Iowa City on June 24, elected the following officers: *President*, Dr. A. Crawford of Mount Vernon; *Vice-President*, Dr. J. B. Kessler of Iowa City; *Secretary*,, Dr. C. E. Murray of Cedar Rapids; *Treasurer*, Dr. George P. Carpenter of Cedar Rapids.

Obituary Notes.—Dr. Samuel K. Harriman of Providence, R. I., died at the Rhode Island Hospital on June 20, aged 64 years. Dr. Harriman was a graduate of the Jefferson Medical College. He had practised medicine in Natick, Mass., and for the past twelve years in Providence. He was a member of the Massachusetts and Rhode Island State Medical Societies.

Dr. John W. Pray of Northwood, Mass., died at his home on June 20, aged 60 years. Dr. Pray was a graduate of Bowdoin College and the Harvard Medical School in the class of 1887. He had practised in Northwood since his graduation.

Dr. C. H. Davidson of Brigham, Utah, died on June 12 of gastric carcinoma. He had practised for many years in that city, but had retired from ill health a year ago.

Dr. Frank H. Wallace of Boston, Mass., died at his home on June 27, aged 50 years. Dr. Wallace was a graduate of Dartmouth College and of Dartmouth Medical School in 1886. He had practised in Boston for eighteen years and was a mem-

ber of the American Medical Association and the Massachusetts Medical Society.

Dr. Ambrose S. Everett of Denver died June 24, 1909, of heart failure at the age of 68. Dr. Everett served through the Civil War with the rank of captain, and at the close of the war studied medicine in St. Louis and went to Denver in 1879. He was the first president of the Loyal Legion of Colorado and was on the staff of a number of hospitals there. He was at one time county physician, and was extremely well known both politically and socially.

Dr. J. L. Henson of Clayton, Ga., died at his home on June 20, 1909, aged 55 years, of Bright's disease.

Dr. Charles M. Dodge died at his home in Manchester, N. H., on June 19, 1909, aged 62 years. He was a graduate of the New York University Medical College in the year 1877. After two years in Amherst, Mass., Dr. Dodge moved to Manchester, and in his thirty years' practice became one of the best known physicians in that city. He was a member of his County and State Medical Societies.

Dr. Albert Prentice Ryall of Shelbyville, Tenn., died on June 19, 1909, aged 69 years. He was graduated from the Medical Department of the University of Pennsylvania in 1866.

Dr. Thomas D. Greenley of Louisville, Ky., died on June 25, aged 92 years. He was the oldest practising physician in Kentucky, and had been in practise for 63 years. Dr. Greenley was a former president of the Kentucky State Medical Association and a member of many societies.

Dr. R. B. Lamb of Ysleta, Texas, died at Providence Hospital, El Paso, June 22, 1909, from typhoid pneumonia. He was 28 years of age and was a graduate of the University of North Carolina and the University of Maryland.

Dr. Gerald B. Garrigan of New York died suddenly of heart disease in Troy, N. Y., on the night of July 3. Dr. Garrigan was a graduate of the College of Physicians and Surgeons, New York, in 1902, was Adjunct Assistant Attending Physician to Bellevue Hospital, Surgeon to Bellevue Out-Patient Department, and Gynecologist to St. Vincent's Hospital Dispensary. He was a member of the American Medical Association, the State and County Societies, and the St. Vincent's Alumni Association.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIOACTIVITY AND CANCER—SIR T. BARLOW ON DAYLIGHT—TYPHOID—MISTAKES IN DIAGNOSIS—SLEEPING SICKNESS—LISTER'S WRITINGS—THE ANTARCTIC EXPEDITION—OBITUARY.

London, June 18, 1909.

The Croonian Lectures at the Royal College of Physicians this year are being given by Dr. S. Lazarus-Barlow. His subject is "Radioactivity and Carcinoma," and he treats it as an experimental inquiry, as becomes the director of the Cancer Research Laboratories at the Middlesex Hospital. In his opening lecture, on Tuesday, he said the leading idea throughout his researches had been that a number of examples were known in which workers with *x*-rays had suffered from cancer in the hand. It had long been held that physical agents might cause cancer in certain regions of the body, eg., clay pipes in the lips, and so on. Approximating these ideas led to the inquiry whether these supposed causes might be real causes on account of an underlying factor, namely, radioactivity. As to this, the first point to consider was, what are the criteria of radioactivity? They are two—photographic and electrical. The first give skiagraphs; the electrical are concerned with the effect on the gold-leaf electroscope. By interposing a screen between radioactive substances and the electroscope we could separate certain forms of radiation. Dr. Lazarus-Barlow then stated the results of some experiments on human tissues. He said if they put human liver, dried at 100° C. and powdered, on a photographic plate in the dark and after a certain time developed, they would find an effect had been produced. The position of the powder would be shown by a deposit of silver. That effect was not due to light and it was not a skiagraph. He would like to call it by a new word—skotograph. He said this skotographic power was present in malignant and in nonmalignant tissues, but did not exist throughout. He said it was not a common property of matter. In fact, substances could be divided into groups which did and which did not produce this effect. He showed plates showing the skotographic effects of tissues with and without carcinoma.

Sir Thomas Barlow has been giving evidence before the Select Committee on the Daylight Saving Bill. He is in favor of it on medical grounds, as he thinks it would afford working people the opportunity of more healthy life—more open air, more sunshine, etc.—especially in large towns. In these there was a continual shrinkage of available open air and sunshine, on account of the crowded dwellings, the long hours in workshops, factories, and offices, all of which were apt to be dusty and badly lighted, often by artificial light only. The most important means of neutralizing the ill-effects of exhausting indoor occupations were sunshine and open air. Town life tended to anemia and outdoor life not only improved the blood but increased the power of resistance of various organs to damaging influences. People on the border line of health and prone to consumption were helped to become efficient by any increase of fresh air and sunshine. By lessening the used artificial light in workshops and offices the bill would tend to safeguard the eyesight of work people. Then the bill commended itself to him from a medical aspect, as it would certainly give more opportunities for open air games and military drill and gymnastics, while older people might engage in gardening, etc. The general result would be in some definite degree to increase the opportunities of all for living a more open air life. Nobody, he thought, could doubt that the bill would be advantageous from the standpoint of civilization and culture, as well as contributing somewhat to the health of the community.

At the Medical Section of the Royal Society of Medicine, on the 25th ult., Prof. Hewlett reported the use of an antiendotoxic serum in typhoid. It was made by the injection of the horse with typhoid cell juice. It had an active neutralizing power against typhoid endotoxin and the typhoid bacillus. Tried in nine cases, it was thought several were benefited and in two the disease cut short. In some cases instillation gave a reaction similar to Calmette's.

Dr. Goodall read an account of 26 cases thus treated, in only 9 of which did it seem to do good. An ophthalmic reaction was given in a few cases only.

Dr. Bruce reported five cases treated in the Fulham Hospital with the antiendotoxic serum and his impression was that two were benefited by the injections.

Lieutenant-Colonel Semple has exploited to some extent the therapeutic application of bacterial vaccines in enteric fever and thinks it worth further consideration. The principle involved in this method is the same as that which underlies prophylactic inoculation—it consists in setting up the process of immunization Early treatment is necessary if good results are to be obtained; that is, it must be begun before marked tissue changes have taken place. Only a small dose should be used, so that the negative phase may not be induced. It is generally thought that autogenous vaccines give better results than stock vaccines, and Colonel Semple is inclined to this opinion from the results of two cases which he treated from vaccines prepared from their own microorganisms, as compared with seven others in which stock material was employed. So far Colonel Semple concludes that the method increases the bacteriotropic elements in the blood, and this would seem to be shown by the increased opsonic index reported. Colonel Semple has communicated the full details and the technique involved in a preliminary contribution to the Lancet. In proper doses he finds the method devoid of risk, and

says it need not interfere with other treatment that may be thought desirable. His nine cases cannot be said to give any indication of a power of cutting short typhoid. But marked improvement was observed to set in after the inoculations in six of the cases—most marked in the two treated with autogenous vaccines—and in the other three cases amelioration of the clinical symptoms was noticed.

Cases of mistaken diagnosis are always instructive, but are not frequently brought forward for discussion. C. W. Cathcart exhibited on the 26th ult., at the Edinburgh Medico-Chirurgical Society, one of supposed malignant disease in the abdomen in a man of 32. He had had severe pain following influenza, which subsided, but returned three months prior to his admission to hospital (December, 1908), when he was very ill, but had no gastric symptoms. The abdomen was explored and a large nodular mass discovered, firmly adherent posteriorly. It could not be removed and was believed to be a malignant growth in the abdominal wall. After recovering from the exploration, he was sent to the Hospital for Incurables and began to improve steadily and rapidly. The man is now regaining health. Unfortunately, no microscopic examination of a portion of the growth was made, the case appearing so obvious that it was not thought necessary to detach any for this purpose. Had the case been treated with drugs or fallen into the hands of a cancer quack, it would have given rise to obvious difficulties and erroneous statements.

The Sleeping Sickness Commission in Uganda seems to have advanced a step in our knowledge of the life history of the trypanosome. Sir David Bruce has written home that the experiment of Kleine has been confirmed as to the period during which the glossiria can pass it on to another animal. It appears that the parasite must remain in the fly for a fixed number of days—16, 19, 22. Such seem the times necessary for the trypanosome to attain the development of its obnoxious activity. If it be proved to undergo periods of dormancy and activity, that would bring it into some relation with the malaria parasite.

Lord Lister's "collected papers" have appeared in two volumes, in accordance with a decision arrived at on his 80th birthday by a committee of his admirers and friends, who secured his approval of the project. The interest attaching to them is to many of us chiefly personal, but to the mass of the profession at home and abroad it is historical, for these papers show the successive steps by which the great Listerian revolution has been accomplished. The contents of the work are arranged under four divisions—(a) papers relating to physiology; (b) to pathology and bacteriology; (c) general surgery and the antiseptic system; (d) general addresses and lectures. You will probably have seen the volumes before this reaches you and I doubt not you will agree with me that it is a worthy record of a remarkable life.

The reception of Lieutenant Shackleton after his Antarctic exploration has been intensely enthusiastic and the papers are full of various details. The medical officer of the party, Dr. Marshall, reports that in the intense cold, ten to twenty degrees below zero, dysentery was the commonest disease among them, though differing from that of hot climates and happily not leaving ill effects. The worst effect of the cold was when they ran short of provisions.

Lieutenant Adams lost an eye from accident on the ship. At the critical moment Dr. Marshall found the surgical instruments were stowed away in the hold. Is it not strange how often, when unlimited forethought has been given to an undertaking, some trifling oversight seems bound to occur? Certainly one might have expected instruments for emergencies would have been easily accessible.

Fred N. Hume, medical superintendent of the Northwestern Hospital, has died suddenly at the age of 58. He had held several other appointments and had extended experience at home and abroad, was attached to the Ambulance of the National Aid Society in the Servo-Turkish and Servo-Russian wars, was director of the English Hospital, Belgrade, 1885-1886, and received the orders Takova, Medjidieh, and St. Sava, besides medals.

The death has also occurred of Dr. Rob Ives Metcalfe, consulting physician to the Beccles Hospital, where he practised many years. He graduated M.D. Edin. 1858, having taken the English College of Surgeons' membership the previous year.

LETTER FROM ATHENS.

(From An Occasional Correspondent.)

THE GREEK CONGRESS ON TUBERCULOSIS—MALARIA AND TUBERCULOSIS—A MONUMENTAL WORK ON MALARIA.

ATHENS, June 1, 1909

I ARRIVED in Athens just before the opening of the Greek Congress on Tuberculosis, which was held in this city the middle of May. The opening session was addressed by the Crown Prince, under whose patronage the Congress was held, and the Queen and Crown Princess Sophia were among those in attendance.

One of the most interesting papers read before the Congress was entitled "Malaria and Tuberculosis." The author, Dr. Cardamatis, showed that malaria could not be considered as predisposing the organism to tuberculosis, and he enumerated the following reasons: (1) Because tuberculosis until recently was a disease of the great centers of population; (2) because we find in comparing the mortality statistics of tuberculosis with those of malaria—of different cities of Greece—that the number of deaths from tuberculosis is small and the number of deaths from malaria is large; (3) if malaria did predispose the organism to tuberculosis there would have been a parallel in the statistics of the two in the malaria centers this long time; (4) because the workers in the mines, or in the open air, or in the factories, while afflicted with malaria, are rarely attacked by tuberculosis, and (5) because while in Greek country districts especially afflicted with malaria the death rate from tuberculosis amounts to 31 in 10,000 inhabitants; in European country districts afflicted with malaria the death rate from tuberculosis till ten years ago was from 31 to 41 in 10,000 inhabitants.

There is no country on the face of the earth—Italy and Africa not excepted—which suffers more from malaria, the yellow plague, as Cardamatis calls it in a recent publication, than Greece. In a voluminous work on paludal fevers Dr. Cardamatis has given the result of twenty years' assiduous labor by himself and the Antimalaria Committee—labor based on the great discoveries of Laveran and Ross of the specific cause of malaria and its transmission through the anopheles mosquito. Here is presented with thoroughness and completeness the entire field of our knowledge of the history, etiology, and prophylaxis of malaria, giving the universally accepted facts brought to light by the studies of the natural history of the mosquito, the microscopical observations in the laboratory, and the practical labors in combat with the disease. Of special importance is the exhaustive account of the work done by Greek physicians. Here we find the study of thousands of clinical cases and of 9,440 microscopical observations divided in groups. One of these is devoted to the study of malaria in children, one to the study of hemoglobinuria. There is a chapter devoted to the study of malaria among the birds in Greece, giving not only all that has been known thus far on this subject, but also 1,000 original bacteriological and histological observations on birds of Greece of different kinds.

The author has presented a copy of his book to the New York Academy of Medicine.

The works on Hygiene and Physiology of Sabba and this book by Cardamatis represent well the state of scientific medicine in Greece.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 24, 1909.

Dangers to the Child in Operative Deliveries.—S. A. Houghton found that of 1,008 deliveries at the Boston Lying-in Hospital in 1907 and a part of 1908 58 were low forceps cases, 44 high forceps, and 37 versions. The same number of cases fifteen years ago gave 78, 7, and 13 respectively. He says that a long first stage due to uterine inertia and not to obstruction injures the child in the slightest. Every method should be employed to get the head into the pelvic brim before we use compression and traction on it. In the institution named with the decrease in low forceps cases and the increase in high forceps and versions there has been an increase of nearly 100 per cent. in the still-born babies and in the deaths in the hospital. The paper is a plea for a more careful recognition of the rights of the child at the time of delivery and a greater judgment in the selection of mothers for whose relief the forceps may be used on the child.

Symptom-Complex of a Series of Exanthematous Diseases. Or Is There a New Contagious Exanthem?—J. W. Watson concludes in this issue an elaborate article with the following statements: (1) Years ago smallpox

and chickenpox parted company. Measles, German measles, and scarlet fever have long since been separated into distinct entities. Recently German measles and Duke's (or fourth) disease have gained a certain amount of individuality. This being the evolution of the exanthems, might not the existence of two diseases (scarlet fever and possibly "The Fifth Disease"), under the name of scarlatina be an unrecognized condition? (2) Seventy-five cases presented and called by many as rubella, and by a few as scarlet fever, even though it is more suggestive of the latter than the former. It has an incubation period of seventeen to twenty-one days, which was easily determined from its existence in isolated places in the country and the source of contagion being absolutely known. (3) Not contagious at all until peeling takes place. Compare this with scarlet fever, which has come upon a physician within a half hour while he is making the examination. (4) The desquamate is sometimes very profuse, but its germ is short lived. (5) Patients are much more comfortably sick than they are with scarlet fever. Sickness does not usually last longer than three days when complications are absent. (6) It has complications and sequelæ. Patient should be kept quiet for two weeks to prevent them. (7) No chance of mixed infection in any of the cases. Some of the severest cases sprang from an initial mild case. (8) Opinions of health officials (State, town, and nearby towns) vary as to the disease. It was generally regarded as very mild. Result: lax quarantine and spread of the disease. (9) Several cases had already had scarlet fever, measles, and German measles, but were not immune to this disease. (10) The bacteriology is a study yet incomplete, but it shows that the germs present have little vitality. (11) It has no long-continued bad after-effects like scarlet fever. (12) In the eighty cases discussed there were no fatalities from the disease. (13) Several physicians and members of health boards have had cases that strongly resemble this disease. There is a marked difference, they say, between it and scarlet fever, and they feel that physicians err in calling it by the latter name. (14) The disease should be rigidly quarantined until desquamation ceases. It is not necessary to quarantine other members of the family, as the disease does not appear to be transmissible through the agency of a third person, nor is it necessary to quarantine as long as in scarlet fever.

New York Medical Journal, June 26, 1909.

The Clinical History of Some Cases of So-Called Cardiac Epilepsy.—R. C. Newton gives the histories of five cases, four of which were under his personal observation, and comments on the attitude taken by various authors of the present time in reference to this class of patients. In Case 1 the patient, a man of 45 years, suffered from spasms of angina pectoris and the autopsy showed cardiac dilatation and hypertrophy with myocarditis, valvular changes, atheroma, and calcareous deposits. He had also had night terrors and epileptic seizures, but it is not so easy to explain these in the absence of post-mortem examination of the brain. In Cases 2 and 3 the angina succeeded the epileptic attacks. In Case 4 seizures seemed referable to indiscretions in eating, and thus far there have been no anginoid attacks. Case 5 presented the Stokes-Adams syndrome. Newton comments on the fact that only one of his cases had a notably slow pulse. He says that numbers of slow cases have been reported in people in excellent health and free from any untoward symptom. So it seems, he continues, that another medical superstition is likely to be demolished and that when bradycardia is coincident with epilepsy the conjunction may be purely accidental. Many authorities maintain the same attitude with reference to the incidence of cardiac diseases and epilepsy, but the author does not take this ground, and considers that cases such as he has reported prove that the cardiac condition is the cause of the epileptic attacks.

Baldness.—J. O. Cobb attaches much importance to the modern hat as a cause of baldness. Pressure upon the scalp should be removed in every way possible. Some one ought to invent a hat which will prevent baldness, though the idea will probably not become popular because there is more money in hair tonics, and hair restorers, and fake electric massage apparatus than in some new kind of a hat which will prevent the disease. Hundreds of remedies are on the market which are advertised as sure hair restoratives, but not one of them will bring back one hair once the hair follicle is atrophied and functionless; nor will any of these remedies prevent the falling of hair unless the habits of the sufferers are changed. At best these remedies are merely skin irritants, which promote a slightly increased flow of blood to the scalp. Dandruff cures are mostly fakes, pure and simple. The only good in the world accomplished by these medicaments is the scalp massage indulged in while applying them. The time to cure baldness is before it begins. Every man should devote a short time before he goes to bed, and after he gets up in the morning to scalp massage, which he can apply himself. During the brisk friction he should grasp his hair in handfuls and draw the scalp back and forth many times, to make it slide over the skull. That will prevent binding and thinning of the scalp and preserve the cushion of fat on the top of the head. It will also pull out the loose hairs, which shed naturally, and which are quickly replaced by a more vigorous growth. A woman in combing her hair cannot help pulling her scalp back and forth, and this very necessity, which she cannot prevent, is the salvation of her most beautiful and most precious adornment. The hair should be worn as thick as nature will allow it, and long enough for the cut ends to extend below the hatband zone. But all these personal attentions will be futile unless one uses the greatest precaution in wearing the hat. Every few minutes, when outside, the hat should be lifted from the head and gently replaced. The hat has a tendency to settle down on the head very snugly, and the indentation from the pressure of the hatband is quite noticeable on the forehead. Hats like the stiff straw, which are easily blown from the head, should never be worn at all, for, in spite of one's self such a hat will be jammed down on the head actually tight enough to seriously impede the circulation.

Indications for Operation in Acute Mastoiditis.—E. Danziger says that in this disease we have three conditions present: First, there is a retention of secretion either serous or purulent; second, there may be a real osteitis, and third, an infectious thrombophlebitis of the smaller veins of the mastoid process. The main clinical symptoms are fever, pain, local conditions, and bacterial flora. If we have to do with a case in which the fever has a tendency to go to 105° and beyond with chills and sweats we have a thrombophlebitis to deal with. The case is a surgical one from the beginning. Mere fever of itself is no necessary indication for operation. As to pain, if after paracentesis the condition improves and later the pain becomes more severe at night and boring and is present without pressure we have to suspect that the mucoperiosteum has been partially destroyed and that the nutrition of the bone is becoming interfered with and that necrosis is taking place. In this connection, the amount and character of the discharge are also of importance. If the amount of pus at such time, instead of becoming less, increases in quantity and drains through a good sized opening in the drum, if it becomes more yellowish, and assumes the character of bone pus, we may safely assume that there is a disease of the bone proper, which indicates surgical interference. It is different in very young children, where the mastoid process is practically a solid bone with one large cell—namely, the antrum, and, as explained before, the pus may travel directly underneath the cortical periosteum without destruction of bone. Sometimes simple drainage through the drum will relieve this condition. An important indication for operation is the sinking down of the upper posterior wall of the external meatus, which indicates an edema due to an osteitis of the mastoid process. Bacteriological examination of the pus, while not giving a direct indication, will put us on our guard, as with detection of the pneumococcus or the staphylococcus we are justified in taking a more conservative stand, while in the presence of the streptococcus, especially the *Streptococcus mucosus capsulatus*, we should interfere surgically as soon as the slightest doubt arises.

No Free Hydrochloric Acid in the Stomach.—R. B. Faulkner refers to the conflicting statements in the textbooks on this subject, which is a bone of contention between chemists on the one side and medical writers on the other. The chemists maintain that free hydrochloric acid is never found in nature, except as an occasional volcanic product, while medical writers assert that it is always present in the human stomach. The chemists say that to determine its presence in the human stomach is extremely difficult, if not impossible, and if possible at all, it can be accomplished only by chemical analysis and by an expert analyst. He comments on the unreliability of the customary tests for HCl, and he finally quotes Hay as saying that free HCl is never present in the human stomach, unless introduced from without; that it would seriously damage it if present; and that it is impossible for it to be found in the stomach, for the reason that its liberation from a salt of any kind requires the presence of a concentrated acid, and any concentrated acid in the stomach would quickly destroy the organ. Concentrated acids are not secreted by the stomach. Free mineral acid is not a

product of the stomach of man or animal. Its absence is not a sign of cancer. The researches of Rogers, Smith, Hay, Dalton, Claude Bernard, Robin, and Verdeil, all original investigators, entirely agree. The data presented by them are in strict accord with the facts and principles of analytical chemistry.

Journal of the American Medical Association, June 26, 1909.

Ophthalmology and General Practice.—A. A. Hubbell speaks of the insufficient attention given to ophthalmology in medical schools and the too limited qualifications of the general practitioner in this line. Too many physicans are inclined to dismiss eye cases, and the result is the encroachment of the still more unqualified commercial "optometrist." There is some complaint also to be made of the professed ophthalmologist who too often begins his work as a specialist with a too superficial knowledge of the subject and without experience in general medicine. The tendency to separate ophthalmology from general practice too exclusively is also a harmful factor, as is also the lack of any legal qualifications beyond that of the general practitioner for any specialty. As to the remedy, Hubbell says that we can first strive to disabuse the public, the profession at large, and the medical school authorities that ophthalmology is so suited to exclusive study and so separate from other departments of medicine that it should be set off by itself and made only a voluntary subject for study and practice. It is not difficult to comprehend, and the diseases of the eye are the last that should be excluded from the physician's practice, as they are to be found everywhere, and with an ordinary knowledge of the subject the general practitioner can do very much good and render to his patients the assistance they are entitled to expect. Accompanying a change in public and professional sentiment in this way there should be a corresponding change in medical teaching which will enable the general practitioner to acquire a sufficient amount of ophthalmic knowledge to meet his future needs as a family physician. The subject should not be a voluntary one in his medical course and it should be sufficiently taught to qualify the graduate to treat all ordinary and infectious diseases of the eye, to distinguish between mild and severe ones, to treat injuries of the eye which are superficial and uncomplicated, and to examine for refraction errors and correct at least the simple forms. He would add also a supplementary examination by the State board covering these points, the successful passing of which would be one of the conditions for license to practise. This would be a check to any neglect on the part of medical schools. It is unfortunate that no qualifications for practice have heretofore been required of the ophthalmologist other than those of the general practitioner. The absence of these and the presence of a dominant spirit of commercialism have, on the other hand, caused in many cases too much haste in beginning this special practice after finishing undergraduate work, with perhaps a few weeks in postgraduate studies. Ophthalmologists are increasing in number and the unqualified ones are also increasing in number. In order that protection may be secured against unqualified ophthalmologists he suggests that the course and subjects of study shall be regulated by law, and that special boards of examiners should be appointed to determine his fitness for practice and authorize a license in this specialty. But the qualifications that it should demand are extended and thorough postgraduate study of every new subject bearing on ophthalmology, personal experimental study in the laboratory, and personal clinical work in a hospital or in his preceptor's private office. He offers these propositions to the section and, if accepted, recommends the appointment of two committees, one to determine the amount of qualifications to be demanded of the general practitioner, and the other to determine and secure the necessary changes and the qualifications of the ophthalmological specialist.

Whooping Cough.—C. R. Grandy remarks on the slight importance attributed by the laity to whooping cough and its partial justification by the attitude of the profession toward that disease. He quotes the statistics, showing that it is really a very serious matter in children under five years of age, being indeed more fatal than scarlet fever. It does not help the matter to attribute deaths to bronchial pneumonia or other purely secondary complications. As Forchheimer says, "In few diseases can so much be done by prophylaxis; in few is so little done." There are difficulties, however. In older children it does not seem a very serious disease. They do not feel very ill and want to be outdoors, and the air and exercise are good for them. Moreover, the disease is infectious from its very onset, and, while the children themselves are kept from school, their brothers and sisters are allowed to continue their studies through the possibly most infectious catarrhal stage and are almost sure to infect schoolmates with infant brothers and sisters at home. Grandy thinks that the first step in prevention will be to teach the public, by a campaign of education, the true seriousness of the disease. The first actual step with the individual case should be prompt notification to the health department. The house should be placarded and the family instructed how to prevent the spread of the disease. If the children are allowed to go in the parks they should wear a conspicuous badge labeled whooping cough and the privilege of going in the public parks be withdrawn if they insist on associating with other children. A better place would be a public hospital outside of town, where such children should be sent. Any pupil in the school who has been exposed should be immediately sent home by the teacher, who should also notify the health officers, and placard and quarantine should not be withdrawn until six weeks from the onset have elapsed and the whooping and expectoration have ceased. Disinfection should follow. Prompt diagnosis will still be a difficulty, but as soon as whooping cough has appeared in a town physicians should be warned that a dry cough without chest signs, little or no fever, and a lymphocytosis is sufficient for a diagnosis, and such an early diagnosis may be enough to stop a considerable epidemic.

A Pragmatic View of Christian Science.—E. C. Wilm objects to the conclusion that the therapeutic success of Christian Science—so-called (for Eddyism, as he thinks, would be a more appropriate name)—has nothing to do with any religious system whatever. He explains that the process of suggestion by which these therapeutic results are accomplished may in certain persons with special theologic and mystic tendencies that have not been corrected by education, produce a state of mind that is most effective and possibly the only method by which the desired health and happiness can be secured. Of course what may be one man's meat may be another's poison, and the faith or credulity, if one wish to call it so, may lead to neglect of necessary life-saving measures. Christian Science is illogical; scientifically it is wrong from beginning to end, but it is one of those views, and they are many, which pragmatically considered frequently appear to serve practical purposes and be apparently right and worthy of philosophical consideration.

Sleep and Digestion.—G. M. Niles discusses sleep and its relation to digestion. As to the actual influence of sleep on digestion, however, there is some conflict of opinion, and he endeavors to cover the subject in a manner helpful to those interested in practical dietetics. It is a well-known physiological fact that the elimination of carbon dioxide and absorption of oxygen are diminished during sleep, mainly because the muscles are less active. Tigerstedt places the ratio of metabolism between the sleeping and waking states as 100 to 145, but asserts it to be dependent on cessation of voluntary movements; "for it may reach just as low a level in the waking conditions, if the muscles be completely relaxed and every voluntary motion suppressed." While other secretions are diminished during sleep, this does not apply to those of the digestive apparatus. When the brain is alert, the reflexes on guard, and the voluntary muscles at work, each department of the human economy is calling for its quota of innervation and blood; these different departments are exacting their tribute from the constructive forces, and turning over to the excretory organs the products of combustion and waste. During this period the digestive department can draw only a "working interest," not being permitted to put away any appreciable surplus, until the day's activities are ended. Sleep stills the voluntary movements, decreases the carbon dioxide output, and makes the least demand on the involuntary vital mechanism. It is then that Nature, our industrious handmaiden, begins her constructive housekeeping. "She does it in an orderly cooperative way, following a regular method of work in repairing waste, actively forming new tissue, and giving just the proper amount of care and nourishment required of all parts, both mental and physical, in regular sequence." Niles does not advocate heavy meals at night, or articles of food

calculated to tax digestion, but states that a certain amount of food in the stomach, the digestion of which, in drawing from the brain a portion of its blood, keeps busy the nerve centers concerned, indirectly quiets other nerve centers which otherwise might exert a wakeful influence. Many sufferers from insomnia well know the happy effect produced by taking hot milk or cocoa, or a light repast just before retiring. The following are some general suggestions as to dietetic recommendations in relation to sleep: The young infant cannot get too much sleep, and this is best attained by filling his stomach at stated intervals. Vigorous, growing children and those engaged in manual labor thrive on a full breakfast and dinner, these two meals containing most of the daily quota of protein. The supper may be plentiful in quantity, but should consist of such articles as bread, milk, cereals, eggs, fruit, etc., which do not unduly stimulate the nerve centers by their metabolic products. Soups, rich extractives, and solid proteins also cause the bladder to be filled with urine rich in waste products and very acid, this being a factor worth considering. Those who labor with their brains, or skilled artisans whose crafts demand mental tension and but little muscular effort, will find their efficiency best subserved by a light breakfast, a slightly more plentiful lunch, and at the close of the day's work a generous meal, provided that after it three to five waking hours are allowed, so that the psychic reflexes may have an opportunity to contribute their share to the processes of digestion. For the leisure class or those who keep late hours and often burn the candle at both ends, it is advisable to take a light repast in bed at 10 A.M. to 12 noon, a hearty dinner at 5 to 8 P.M., and a moderate supper, with not too stimulating or alcohol-containing beverages at 11 or 12 P.M.

The Lancet, June 19, 1909.

Removal of Superfluous Hairs by Improved Methods.—A. H. Pirie says that much misunderstanding exists as to the proper use of the electric current in removal of hairs. The hair-root is not burned by the electricity as a nevus is burned by a cautery point, but acids and alkalis are formed at the respective poles, and it is these which do the actual work of cauterization and destruction of the hair-root. A corrodible needle should never be attached to the positive pole, otherwise pigmentation may be produced. Care should be taken to avoid the scarring of the skin. This may be accomplished by having the needle insulated to within one-sixteenth of an inch from the point. This in turn may be done by holding the needle red-hot in a piece of shellac except for the one-sixteenth near the point. When the needle thus insulated is thrust into the hair-root the acid attacks only the root, and there is consequently no scarring. Better results follow the employment of fine wire, which will find its way down along the side of the hair into the skin, and in case of hairs whose roots take a curved course the wire follows the curve instead of making a false passage, as the finest needle will do. To sum up, the essentials of good results are: (1) connection of the wire with the negative pole, (2) use of fine, stiff wire as a needle (the wire supplied with the finest hypodermic needle is a suitable one), and (3) the insulation of the wire so that only one-sixteenth of an inch of the end is uncovered. The advantages are absence of scarring and a lower percentage of regrowth of hairs.

Treatment of Chronic Suppuration of the Maxillary Antrum; An Operation and New Instruments.—J. Donelan presents illustrations and descriptions of instruments designed to enter the antrum from the nasal side. These instruments are similar in principle, though not in exact shape, to those designed for the same purpose by Abraham of New York and consist of a chisel and a curved gouge. Donelan says he has never removed the anterior half or third of the inferior turbinate, as advised by many authors. This part of the turbinate bears only rarely any relation to the maxillary antrum and then only a very small and useless one for surgical purposes. The antrum in the vast majority of a large number of skulls examined by him, when present at all, is in relation to the second or even the third molar tooth and its greatest width will be constantly found in this situation. On the other hand, the anterior third of the inferior turbinal, which is that portion attached to the inferior turbinal crest, corresponds to the solid origin of the nasal process of the superior maxilla and the dependent fleshy portion in all but the negro races is almost constantly in a line with the nasal border of the superior maxilla. Moreover, when this portion of the turbinal corresponds to any portion of the antral cavity, it does so only when the latter is extremely shallow and if a curved trochar is pushed there is very great danger of wounding the anterior wall or even the cheek.

The Operation of Cardiolysis, Illustrated by a Case.—This subject is discussed by F. J. Poynton and W. Trotter, who note that in 1902 Brauer pointed out that in certain cases of adherent pericardium, where the heart is embarrassed by fixation to the surrounding parts, a considerable amount of the heart's overloading could be gotten rid of by rendering the precordial portion of the chest wall more flexible than normal by removing its bony and cartilaginous framework. No extensive separation of adhesions was urged, and in fact such a procedure would be distinctly dangerous. It is generally agreed that only those cases are suitable for the operation in which the heart has shown some capacity for recovery by rest in bed. The most suitable cases seem to be those in which the heart is just inadequate for active life. No profound general anesthesia is required and from published cases it may be believed that this part of the question is free from difficulty. Chloroform has been employed in the cases thus far reported. If the operation is required at a time when the heart is not at its best, local anesthesia would doubtless suffice. Technical details are simple. A horseshoe-shaped flap should be marked out, having its base above the third rib and its apex at the seventh. The inner edge should be over the sternum and the outer in the region of the nipple. The flap is turned up with the pectoralis and all the structures external to the ribs. The fourth and fifth ribs are those most commonly excised, but the extent of the rib resection will depend, of course, on what is found. A length of at least three or four inches of combined rib and cartilage must be removed. The third, sixth, and even the seventh rib must be dealt with if it appears called for, and even the edge of the sternum has been excised. One successful case is reported.

Pancreatic Glycosuria Ten Years After Typhoid Fever.—A case of this nature is reported by P. J. Cammidge, whose patient was a man of 51 years. He was evidently a typhoid carrier, for his feces, examined at the end of ten years after his fever attack, showed bacilli practically corresponding in culture reactions to those of the *Bacillus typhosus*. The author says that pancreatitis is an uncommon sequel of typhoid, but in this case he believes that the glycosuria was set up as a result of pancreatic changes caused by the constant infection of that viscus from the gall-bladder and pancreatic duct. In this particular case ten grains of urotropin and the same amount of sodium salicylate were given thrice daily in two ounces of water for three weeks, when the urine and feces were to be examined again. The author adds that the second indication for treatment would be to discover the patient's tolerance and powers of digestion for the various forms of sugar, starch, fat, and protein, so that a diet could be arranged which, while it threw a minimum amount of work upon the pancreas and combated the glycosuria, would yet supply a sufficient amount of nourishment to keep the patient in good condition. This plan should be controlled by systematic examination of the urine and feces. The ultimate result of the treatment is not given.

Poisoning by Bismuth Subnitrate Injected into a Knee-Joint.—The patient of A. Don, a man of 37 years, with a history of venereal disease and joint affection, but no injury. Right knee was swollen for some months, but several examinations of fluid removed revealed no organism. Calmette's test gave a slightly positive reaction. As the serous discharge was rather profuse the author injected over two ounces of a one to three bismuth in vaseline and applied a rather tight bandage. In thirty-six hours a characteristic bismuth stomatitis appeared. There were no digestive symptoms except anorexia. The joint was evacuated and the ulcers healed up in a week, with the aid of a feeble acid mouth wash and free swabbing with a solution of potassium chlorate. The joint also rapidly improved and to all appearances was quite well in three weeks. The author thinks this experience worthy of record, in view of the frequency of the introduction of bismuth into cavities for diagnostic purposes by radiography.

Clean Midwifery in General Practice.—A. H. Gregson says that it is possible to practice clean midwifery under the most unpromising circumstances He is an ardent advocate of the use of rubber gloves. These

are boiled in a soda solution and kept in lysol or mercury solution. The doctor's hands are washed with soap and water, all the folds of the patient's genitals and adjacent parts are thoroughly cleansed with bichloride and the vagina is swabbed as thoroughly as possible with cotton well wet with the same solution and never dipped into it a second time. Then his hands are sterilized in the ordinary way and the gloves put on without filling them with water, a pad of cotton being used to work them on and the examination made without any lubricant except a one per cent. lysol, contamination from the anus being avoided by covering it with a pad. If instruments are required, boiling water is poured into a tin sterlizer carried by the doctor, the gloves put in and a two per cent. lysol solution added. The whole is then boiled for five minutes with a spirit lamp, half the solution poured into a jug as a reserve and cool added to the tin. If version or rotation of the child is required the lysol is apt to make the gloves too slippery and bichloride solution is added instead. The candid surgeon adds that after it was reported that a certain person must have had syphilis or else he would have not used gloves, he put up a sign that "an extra charge of 2s. 6d. would be made for the use of rubber gloves."

Red Degeneration of Uterine Fibroids Complicating Pregnancy.—J. Bland-Sutton discusses the influence which pregnancy exerts on fibroids. When the walls of the uterus are occupied with fibroids and pregnancy ensues, the fibroids are often influenced by the altered conditions. They often become red or flesh-colored and this has been supposed to be due to an increase in muscular fiber. Another important change is the onset of pain and tenderness. In early stages the reddish change comes in streaks, but as pregnancy advances the whole fibroid mass becomes so affected and the whole fibroid may even soften and become diffluent. In these degenerating fibroids no organisms are usually found, but the tissue is necrotic and refuses to stain. The characteristic redness is found to be due to the diffusion of blood pigment through the necrosed tissues, so that the hardest fibroid may become of the consistency of soft soap. From a large subserous fibroid *Staphylococcus pyogenes aureus* has been isolated, but no organisms have been found in the interstitial variety. It is now believed that when a uterus becomes pregnant the fibroids do not enlarge in consonance with the physiological increase of the normal muscular tissue of the uterus. Some fibroids do enlarge beyond doubt, but this results from interference in circulation in these tumors, producing edema and color change due to hemolysis of blood, not to rapid increase in muscular tissue, as has generally been supposed. The sudden pain and tenderness produced by the red change may suggest rupture of a pregnant tube. If the patient is kept in bed the pain and tenderness due to the red change will generally subside. Occasionally surgical intervention is necessary. During the last nine years twenty cases have come under the author's personal care. Of these the symptoms came on in the first month once, in the second four times, in the third four times, in the fourth six times, in the fifth, sixth, and seventh once each, and in the puerperium twice. Of the patients three were spinsters, three multiparas, and fifteen primiparas. Ages varied from 28 to 45. Of the operations done, three were enucleations and seventeen hysterectomies, two of the latter being total, as the fibroids were in the cervix. The author has seen the red change occur in all thirty-two times. He says that he has no opinion as to its cause. The presence of microorganisms in the degenerated tissue is in all probability exceptional. The thrombus and infarction theories which have been advanced require more proof than has thus far been brought forward. The condition is prone to occur during pregnancy. Fibroids so changed are a serious menace to the pregnant state.

Berliner klinische Wochenschrift, May 31, 1909.

The Diagnosis and Therapy of Bladder and Kidney Tuberculosis.—Casper discusses broadly the subject of tuberculosis of the kidneys and bladder, and summarizes his opinions as follows: Tuberculosis of the urinary tract nearly always begins in the kidneys. Primary bladder tuberculosis is very rare. Urogenital tuberculosis, by which he means disease of the vas deferens, prostate, seminal vesicle and ducts, occurs in about 5 per cent. of all cases of tuberculosis of the genitourinary system. Tuberculosis of the kidneys is at its onset unilateral and usually remains so for years. Diagnosis of tuberculosis of the urinary tract is made by finding the bacilli either by the microscope or by inoculation of animals. It is most important to make an early diagnosis. For this reason each indefinite case of suppuration or hemorrhage from the urinary tract should be examined for tuberculosis. The determination that there is tuberculosis of the urinary tract is all that is necessary at first. The diagnosis of the location and extent of the lesion can be left by the practitioner to the specialist. Every operable case of kidney tuberculosis should be operated on.

The Influence of Hydriatic Procedures on the Size of the Heart.—Selig studied the size of the hearts of a large number of patients before and after various kinds of baths. Groedel's orthodiagraph was used. The results were as follows: Hot fresh water baths caused a decrease in the cardiac area and an increase in the pulse rate, while cold baths caused the heart to increase in size and the pulse to be slower. Both hot and cold baths caused a reduction of blood pressure. Hand baths, of which only two were given, caused the opposite effect on the heart. The cold bath reduced and the hot bath increased the size. Local applications of hot and cold water to the cardiac region gave variable and uncertain results in the heart size, but the cold caused a decrease in the pulse rate and a rise of blood pressure. Carbonized baths were also used. These were also quite variable as to the effect on the size of the heart, though they caused a slight increase in blood pressure and a lowering of pulse rate.

Deutsche medizinische Wochenschrift, May 27, 1909.

The Differential Diagnosis of the Acute Exanthemata.—Heubner in an extensive article considers the diagnosis of the exanthemata, especially in the pre-exanthematous stage. In measles the most valuable indication is the Koplik spots. These appear sometimes on the first day of the prodromal fever, and are distinctly evident by the second day. They last from four to six days. Scarlet fever is often mistaken for diphtheria. The points of differentiation are that the mucous membrane around the angina is redder than in diphtheria, the lymph glands more swollen, the pulse higher, and the odor of the breath sweetish, while in diphtheria it is foul. Variola is suggested by the severe headache and back ache. The prodromal rash may be mistaken for measles or scarlet fever. The lack of Koplik spots and the freedom of the face from rash point to the correct diagnosis. In adults the first rash of measles may be papular and suggest smallpox. "Stomach rashes" in infants may resemble measles, but lack the prodromal and the Koplik spots renders the diagnosis possible. Drug rashes, resembling measles, can be told by the greater itching and occasional urticarial patches. German measles is characterized by absence of prodromals, the slighter rash, more ephemeral temperature, and short duration. Duke's "fourth disease" is discussed at some length. It is probably a clinical entity between measles and scarlet fever. It occasionally resembles one, at other times the other, and in epidemics attacks children who have previously had both. There is no adenitis as in the others. Infectious erythema resembles German measles in its general symptoms, but shows an intensely red butterfly eruption over the nose and cheeks. On the body the rash may appear in circles with clear centers. It itches but little. Serum sickness may take many forms and cause difficulty in diagnosis. Erythema scarlatiniforme desquamativum recidivans is difficult to tell from scarlet fever.

Transient Hemiplegia with Migraine.—O. Renner reports three cases in which the typical symptoms of migraine—dizziness, aphasia, and dancing spots before the eyes—were accompanied by severe right-sided headache and left-sided hemiplegia. The duration of the attacks was brief, and in a few hours the cases showed complete recovery. The attacks recurred at frequent intervals. The author considers that these cases speak for the vasomotor theory of migraine and that the symptoms were caused by a vasoconstrictor cramp of the cerebral vessels.

The Influence of Radium on Uric Acid Salts.—F. Gudzent has found that uric acid forms two primary salts which are isomers. The *a*-salt is more soluble than the *b*-salt but very unstable. The *a*-salt is converted into the *b*-salt immediately in a watery solution. The *b*-salt is stable. Uric acid circulates in the blood only in the form of *a*-salt, especially the monosodium urate. In the blood, on account of the strong sodium in concentration, in accordance with known physicochemical laws, its solubility is much decreased. As such a decrease in solubility is relatively greater the less soluble the substance, the difference between the two isomers is increased in the blood. The author has shown that this less soluble, stable, monosodium urate plays an important part in gout. The author has attempted to transform the stable *b*-salt to the unstable *a*-salt. This he has done by the use of radium

Book Reviews.

Operations upon the Uterus, Perineum, and Round Ligaments. By W. J. Stewart McKay, M.B., M.Ch., B.Sc., Senior Surgeon Lewisham Hospital for Women and Children, Sydney; Member of the Royal Society of Medicine, London. New York: William Wood & Co., 1909.

This is one of the latest and most extended instances of specialization within a specialty. The work deals almost exclusively with the injuries to the genital organs resulting from childbirth, and its object, as stated in the introduction, is to point out how the obstetrician should deal with the immediate lesions or how those should be treated later on if neglected or unsuccessfully repaired. The writer very sensibly insists on the possession of a more accurate knowledge of the mechanics and pathology of these lesions, especially as regards the perineum. For the latter is not, as so often stated, merely a keystone and the supporting structure of the vagina and uterus.

A brief note on each of the several groups of chapters will give the most satisfactory idea of the scope of the book. In the introductory chapter on anatomy, which is exceedingly good, it is clearly shown that the function of the various planes of the pelvic outlet is not only to support the urogenital organs, but also to resist intraabdominal pressure. The pelvic diaphragm, augmented above and below by a stout layer of fascia, bears the brunt of this pressure, and when torn during parturition the lessened resistance to abdominal pressure produces a procidentia of greater or less degree. The reparative plastic surgery of the vagina and cervix is carefully described in the following chapters, the author considering only the well-known and tried operations, thus avoiding the confusion which would attend the inclusion of all the numerous plastic procedures which have been devised. The methods of suspending or fixing the uterus itself are next considered, and the indications for the various well-known operations are clearly presented. The author extends to the Alexander operation much favorable comment. He regards it as the operation of choice in cases where there is an uncomplicated retroversion or retroflexion, and prefers it even where adhesions are present, as the latter can be broken up through the internal ring. It is quite unlikely that this view will find favor among the majority of our American operators at the present day. Considerable space is given to the subject of curettage and its complications, and the concluding chapter is devoted to the operative treatment of dysmenorrhea, for which the writer advocates a cervix-splitting operation.

A word of praise must be said in conclusion for the illustrations, which are exceedingly well done, and clearly demonstrate the various steps in the operations described in the text.

Clinical Diagrams. 25 Sets. Designed for the Graphic Representation of Clinical Phenomena, with the Notes of Cases. By James C. Wilson, M.D., Physician to the Hospital of the Jefferson Medical College. Philadelphia: J. B. Lippincott Co., 1909.

These diagrams consist of printed outlines of the body viewed in different positions. The six diagrams consist of an anterior, a posterior, a right, and a left lateral view of the male body, and an anterior and a posterior view of the female body. All six are printed on one page and can be easily removed one by one along the perforated lines. A chart of accepted symbols for indicating physical phenomena upon the diagrams accompanies the set. It should prove useful in recording the observations made at the bedside, and, while saving much time, should also lead to greater accuracy of the records.

The International Medical Annual. A Year Book of Treatment and Practitioner's Index. Twenty-seventh year. New York: E. B. Treat & Co., 1909.

The book is divided into three parts. Part I deals with the advances made in materia medica and therapeutics in 1908. It opens with a short general review, followed by a dictionary of remedies. Space is given to the consideration of serum therapeutics, opotherapy, Béraneck's tuberculin, opsonins and vaccines, radiotherapeutics, electrotherapeutics, and x-ray therapeutics.

Part II begins with a review of medical and surgical progress in 1908. This section has to do with new treatment. The subject matter is arranged in alphabetical order. Considerable space is given to appendicitis, brain surgery, and the surgery of the gall-bladder, pancreas, and prostate. Professor Lucas-Championnière's treatment of fractures without immobilization is fully described. Among the specialties touched upon are diseases of the skin, pediatrics, gynecology and obstetrics, orthopedics, and the diseases of the ear, eye, and nose. In the section devoted to the nasal accessory sinuses are twenty-three plates, illustrating certain clinical aspects of nasal accessory sinus suppuration. In Part II, under the head of sanitary science, are discussed pure milk supply, food preservatives, sewage disposal, the tuberculosis problem, typhoid fever carriers, and the medical inspection of school children. The various sections have been written by specially selected authors, who are authorities on their subjects.

Text Book of Embryology. By Frederick Randolph Bailey, A.M., M.D., Adjunct Professor of Histology and Embryology, College of Physicians and Surgeons (Medical Department of Columbia University), and Adam Marion Miller, A.M., Instructor in Histology and Embryology, College of Physicians and Surgeons (Medical Department of Columbia University). With five hundred and fifteen illustrations. New York: William Wood & Co., 1909.

There is probably no study so essential and important as a foundation for that of medicine as embryology, and yet it is only in comparatively recent years that attempts have been made in our medical schools to include any portion of it in their curricula. This cannot be ascribed to any lack of knowledge of the facts, for these have been rapidly developed since the initial discoveries made by Schleiden, Schwann, Kölliker, Reichert, and others about 1840, regarding the cell as the basis of animal structure. For obvious reasons it is not possible to study human embryology from human material, examples of the early stages being wanting, but we can gain very satisfactory results with material derived from the lower orders of animals. The deductions drawn from these sources have rarely been found to be erroneous.

The text book here noted is an outgrowth of the course in embryology as given by the authors in the medical department of Columbia University. It was intended primarily to present to the student of medicine the most important facts of development, at the same time emphasizing those features which bear directly upon other branches of medicine. The scope of the work was extended, however, as it took form, in order to make it of greater value to the general student. Practical suggestions are added at the end of each chapter which include brief descriptions of embryological technique as aids to the study of the structures described. In addition there is also an appendix, in which the strictly technical aspects of the subject as regards the procuring, handling, and preparing of embryological material are stated in greater detail.

The book is divided into two parts, the first of which deals with "general development," the second with "organogenesis." The chapters in the first portion deal with the cell and its proliferation, the sexual elements, maturation, fertilization, segmentation, germ layers, fetal membranes, and the development of the external form of the body. The development of the germ layers has been very elaborately treated from the comparative standpoint, because this has been found the most satisfactory method of teaching the subject. Gastrulation is shown in all the lower classes of vertebrates, which is the limit of our knowledge, as no human ovum has been observed in which this phenomenon could be demonstrated. The earliest human embryos which have been studied in sections, those of Peters and Spee, show the three germ layers and the flat embryonic disc, but the preliminary stages have thus far not been demonstrated. From analogy it is possible, however, to construct these hypothetical stages in diagrams, as carried out by the writers.

In the second portion of the book, devoted to "organogenesis," the most extended reference is to the nervous system, the chapter being written by Oliver Strong, a recognized authority on the subject. It is not feasible to go into detail on this point, but the chapter in question constitutes one of the most lucid and interesting expositions of this exceedingly important topic which has come to our notice. The student and practitioner will find in this chapter much valuable information which will serve to clear up some of the many uncertainties connected with the study of neurology.

It is to be hoped that the appearance of this work will lead to greater attention being paid in this country to the importance of the study of embryology in our medical schools. It will serve not only as a text book for the beginner, but may be regarded as a guide for those who may be interested enough to desire a more advanced knowledge of the subject. In typography and illustration the book is excellent, and the few minor errors and omissions will probably be corrected in the future editions which are certain to be demanded.

König's Lehrbuch der Chirurgie für Aerzte und Studierende. IV Band. Allgemeine Chirurgie von Dr. Otto Hildebrand, Geh. Med. Rat. Ord. Professor der Chirurgie, Direktor der Chirurgischen Universitatsklinik und Poliklinik der Kgl. Charité in Berlin. Dritte neu bearbeitete Auflage. Mit 438 Abbildungen. Berlin: Verlag von August Hirschwald, 1909.

The volume on general surgery in the well-known work of König appears now in its third edition, having been revised by Professor Hildebrand. The book has been probably the most popular surgical treatise in Germany, among both students and practitioners, and recently English speaking physicians have begun to recognize its merits. Its chief claim to eminence as a text book is founded upon its completeness and upon the fact that it represents more the results of practical experience in surgery gained in a lifetime of teaching and practising surgery, than a compilation of surgical facts gathered from various sources. The limits of a review do not permit a discussion of the details of the book, but special attention may be called to the divisions dealing with the diseases of the joints and that dealing with tumors. The former contains the well-known teachings of König in regard to the frequency of primary synovial tuberculosis of joints, teachings which are backed up by a large statistical material. The section on tumors is a judicious statement of our knowledge, and our ignorance, in this division of medicine, and is especially valuable for the philosophical breadth of view with which the vexed matter of neoplasms, their causation and their classification, is treated. The personal equation in the book is evidenced by the slight respect with which such new matters as Bier's hyperemic treatment is considered. The volume, however, wins much in individuality by representing the views of one author. We heartily recommend the book to American surgeons, and especially to American students of medicine; for parallel reading while studying surgery, König's book is probably unsurpassed by any other volume on the subject in the German language.

Epoch-making Contribution to Medicine, Surgery, and the Allied Sciences. Being reprints of those communications which first conveyed epoch-making observations to the scientific world, together with biographical sketches of the observers. Collected by C. N. B. Camac, A.B., M.D. With Portraits. Philadelphia and London: W. B. Saunders Co., 1909.

The epoch-making contributions presented in this volume are seven in number. The first is Lister's article, "On the Antiseptic Principle of the Practice of Surgery," which was read before the British Medical Association in Dublin, on August 9, 1867, and which is here reprinted from the *British Medical Journal*. The next is William Harvey's "An Anatomical Disquisition on the Motion of the Heart and Blood in Animals," in Willis's translation. This is followed by Auenbrugger's article on "Percussion of the Chest," translated by Forbes. Following this is Laënnec's "Treatise on the Diseases of the Chest and on Mediate Auscultation," also in Forbes's translation. Then comes Edward Jenner's "Inquiry Into the Causes and Effects of the Variolæ Vaccinæ." Morton's "Remarks on the Proper Mode of Administering Sulphuric Ether by Inhalation," and "On the Physiological Effects of Sulphuric Ether and Its Superiority to Chloroform," together with Simpson's "Account of a New Anæsthetic Agent as a Substitute for Sulphuric Ether" form the next instalment, and the volume closes with Holmes's essay on "The Contagiousness of Puerperal Fever." All of these papers are classic, and should be read by physicians—and this is now an easy matter, thanks to this volume. The portraits add to the interest of the papers, but the biographical sketches are in some cases too brief to be of much value; that of Harvey, for example, occupies only one page.

Sanitation and Sanitary Engineering. By Wm. Paul Gerhard, C.E., Consulting Engineer for Hydraulic and Sanitary Works, Member of American Public Health Association, Corresponding Member of American Institute of Architects, Member Am. Soc. Mechanical Engineers, etc. Second Revised and Enlarged Edition of Sanitary Engineering. New York: Published by the Author, 1909.

This book of 175 pages is divided into five chapters, one of which relates to the sanitation of municipalities, one to emergency sanitation in time of epidemic, calamity, or war; one deals with the advances of sanitary science from the historical standpoint; one is devoted to sanitation as practised in Greater New York, and one discusses sanitation—or rather its lack—in Russia. The subject matter of the book is handled in such an elementary way that neither sanitary engineers nor physicians acting as health officers will probably find much, if anything, between its covers which is new to them. As a source of elementary information for such of the laity as are interested in civic betterment, it may have a certain usefulness, though at times it is misleading.

The author appears to be quite carried away by his enthusiasm for his professional specialty, and, after dividing engineering as a whole into fifteen divisions, he very justly says: "It would be quite impossible for one man to acquire a thorough knowledge and practice in all these branches." In his outline of a suitable course of instruction for the education of sanitary engineers he very properly does not include any subject of a medical nature, yet on page 72 we find him saying: "The duties of the sanitary engineer in time of war will embrace something like the following, viz., * * * 4. The first aid to the wounded on the battlefield and at the dressing stations. 5. The care of the wounded. * * * 6. Care of the sick in tent and barrack hospitals."

Having already appropriated everything of a public health nature as a function proper to sanitary engineers only, in the above quotations he finally proposes, in addition, to eliminate all medical men from service with troops in war, substituting therefor the scarcely adequate untrained medical and surgical service of his brother engineers. This is a rather exaggerated example of the state of mind into which some of his brethren have fallen, who are constantly endeavoring to encroach on the provinces of the medical side of public health work without possessing any more qualifications and training therefor than any other intelligent layman. The general attitude of the author seems to be toward the belittlement of medical men and their functions in relation to health work, and it is well to call his attention to the fact that practically all advances in sanitary science have been made by physicians; and that when sanitary engineers have aided in such advance it has merely been in working out the details of application based upon the scientific discoveries and practical suggestions of their medical confrères. Since he assumes the possession of full qualifications for the sanitary as well as medical administration of military camps, it is somewhat surprising, to say the least, to find the pronouncement, on page 76, "a small field hospital should be erected, either of log huts or tents," when every one knows that field hospitals are essentially mobile organizations, and that the sick should be transferred for treatment to hospitals outside the camp or along the line of communications. He apparently favors the use of excavated latrines in standing camps, which the mere doctors with the army have long since regarded as absolutely inadmissible from the sanitary standpoint.

Finally, the last chapter relating to sanitation in Russia is published as a horrible example. The conditions recounted are in no respect worse, and in many ways better, than those which existed in Cuba, Porto Rico, Panama, and the Philippines, which have been dealt with by army medical men, practically without assistance from sanitary engineers, in a way which has elicited universal admiration and commendation. In preparing a next edition it is hoped that the author will live more up to the good old adage, "Let the cobbler stick to his last"; sanitary engineers will find quite enough to occupy them in the solution of their legitimate problems relating to water supply, drainage, disposal of waste, and building superintendence.

Diseases of the Pharynx and Larynx. By E. J. Moure, M.D., Surgeon in Charge of the Nose, Ear, and Throat Department of the Faculty of Medicine, Bordeaux. Translated and adapted by J. Malcolm Farquharson, M.B., Lecturer on Diseases of the Ear, Nose, and Throat in the School of Medicine, Royal Colleges, Edinburgh, etc. With 210 illustrations. New York: Rebman Co., 1909.

In a condensed form and in flowing English the translator has made more accessible to the profession the well-known text book of Moure which appeared originally in 1904. The cordial reception which the French publication received has rendered the Englishman's task a grateful one. Moure's contributions to literature in the special domain indicated in the title have concerned themselves chiefly with erythematous angina, polymorphous, erythema, pemphigus and acute lacunar, ulcerative tonsillitis, which he has differentiated from acute ulcerative membranous tonsillitis. His classification of tonsillar abscesses is based upon the origin of these suppurations, and especially upon the history of their duration. The whole book is an expression of the results of twenty-five years of special work, and as such merits from every point of view a careful investigation.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, Held at Atlantic City, N. J., June 8, 9, 10 and 11, 1909.

(*Concluded from page 39.*)

(Special Report to the MEDICAL RECORD.)

SECTION ON OBSTETRICS AND THE DISEASES OF WOMEN.

Thursday, June 10—Third Day.

Election of Officers.—*Chairman,* Dr. J. G. Clark of Philadelphia; *Vice-Chairman,* Dr C. C. Frederic of Buffalo; *Secretary,* Dr. F. L. Lewis of Georgia; *Delegate,* Dr. H. G. Wetherill of Denver; *Alternate Delegate,* Dr. I. S. Stone of Washington, D. C.

A Petition to the House of Delegates was offered by Dr. J. Betton Massey of Philadelphia requested the formation of a section on physical therapy, including radiotherapy, electrotherapy, the application of heat, light, massage, water, and other agents.

Cancer of the Uterus Too Far Advanced for Radical Operation.—Dr. HERMANN J. BOLDT of New York City entered a plea for the education of women so that they should help the physician in the early diagnosis of cancer of the uterus. He gave a description of the electrothermocautery treatment of the cervic cancers in the late cases. He said that the women should be taught that no one symptom was characteristic of cancer, and that she must apply to the physician and request examination at the first manifestation of pelvic symptoms at variance with her normal conditions, as shown in any variation from normal menstruation, leucorrhea, and so on. In Germany the teaching by Dürhsen and Winter through the lay press has greatly decreased the percentage of inoperable cases applying for treatment. He would have the American Medical Association appoint a committee to consider this plan of education. That was the only way to lessen the mortality of uterine cancer. The extensive operations had already reached their limit. In the palliative treatment of the inoperable cases some had been reported cured after the application of heat, some after exploratory laparotomy with no operation on the cancer. These were to be considered as spontaneous cancer cures if the clinical diagnosis could be accepted on the authority of good surgeons. Even palliative operation was not always justifiable if it was going to leave the woman worse off than she was before the operation. He considered the palliative use of curette and cautery the most efficacious method of treatment in the extensive cases. He used a large spoon curette to excavate the soft material, and then controlled the bleeding by the dome cautery. The work was done through a double speculum with water flowing between the layers of the speculum to keep it perfectly cool. During the cauterization the uterine tissue was also at times cooled off by packing ice shavings on the parts through the speculum. Later, after the eschar was thrown off, he applied tincture of iodine twice a day until the cavity was contracted. The cauterization was repeated for bleeding or softening of the tissues. He considered the action of zinc too penetrating for common use. Fulguration claimed good results, but still needed the proof of time.

Palliative Treatment of Cancer of the Uterus.—Dr. WALTER B. CHASE of Brooklyn argued in favor of the thermocautery, which he believed the most efficacious treatment. The heat penetrated beyond the actual cautery. He used wet asbestos paper to protect the normal parts from the heat. The cervix was caught by a spreading tenaculum pulled down and a wire loop cautery applied around the cervix, which was then amputated. The dome cautery was then applied to the canal and used to destroy the interior of the uterus. In some cases where cachexia had already developed it cleared up. Douches of permanganate were given for discharge, and granulation tissue controlled by phenol or silver nitrate. Such postoperative local treatment saved a great deal of the pain, as did cocaine locally. Dr. Byrne claimed that 19 per cent. of these cases were alive five years after operation, and this was all the more surprising because he operated on every case that came. Roentgen rays and radium were both effective in the conditions, and radium seemed preferable. He cited five cases treated by cauterization. In one case a pregnancy had begun and gone to term after this amputation of the cervix. Cauterization of the cervix with the dome cautery had been done during the pregnancy. The patient lived a year after the child was born.

Dr. G. BETTON MASSEY of Philadelphia expected soon to hear the last of cutting into cancer tissue with any sharp instrument. The normal vaginal tissue was also injured by heat, and it was difficult to keep the tip of the cautery hot while it was in contact with the tissues. The odor of the separating slough also was very offensive, so that he preferred the electrochemical cautery. He used sharp zinc needles one-eighth of an inch wide, insulated to within an inch of their tip with wax, and then the tip dipped in mercury and then in sulphuric acid. The patient was put in the knee chest position without anesthesia, and then the needles inserted into the periphery of the mass and connected with the negative pole of the battery, while the positive pole was attached to a pad on the patient's back. The treatment was repeated at frequent short intervals if necessary.

Dr. CARSTENS of Detroit used zinc chloride as a caustic and repeated as often as necessary. The principle trouble in these cases came when they broke down and ulcerated and sepsis was superimposed. He thought that the importance of examination ought to be taught by the State Board of Health by a leaflet of information for women.

Dr. FREDERIC of Buffalo said that he would like to see an effort made to save the inoperable cases of cancer. Where the disease had extended beyond the cervix and no operation was useful, the curette and cautery did improve the condition; not a single treatment, but repeated treatments every two months. He had two patients whom he considered cured, and yet they had been thought incurable.

Dr. MCGLINN of Philadelphia said that the most essential point in the treatment of cancer was the early diagnosis. One woman in eight over thirty-five years of age died of cancer in England, and about as many in this country. Cancer was getting to be more extensive than tuberculosis, and was responsible for one-third of the surgical deaths. The women should be educated to come early for treatment, but the physicians also should be educated and taught to appreciate the urgency of early operation in all suspicious cases.

Dr. I. S. STONE of Washington told of a lake where a vast number of the trout were affected with cancer of the thyroid gland. This seemed to point to a parasitic origin, and gave the hope of a serum treatment in the future.

Dr. KELLY of Baltimore said that there were three possible ways of cure. One was to discover the cause and eradicate it, which was not yet feasible; another was to do more radical operations, and that seemed impossible; and the third was to make an early diagnosis, and that was possible through education by the public press. He thought that every woman who had borne a child should be examined once a year, whether well or not, and in that way we might make a diagnosis before symptoms appeared.

Dr. NOVAK of Baltimore said that there were three periods in the cancer history of each case—the first when the woman recognized the symptoms and prepared to tell the physician; this was usually the longest period; second, the time after the woman consulted the physician before he

took her to a surgeon; this often was too long a period, though the general practitioner was learning to act more promptly; the third stage between the surgeon and the operation was usually short. To educate the laity the State of Maryland had undertaken to issue weekly health bulletins in the newspapers, unsigned, but under the auspices of the State Society. The State also had a certain number of health talks. There had, however, been considerable difficulty in getting the newspapers to publish articles on the symptoms of cancer of the uterus, although they did not object in the least to printing advertisements of cures for female weakness. Therefore it had been necessary to turn to pamphlets gotten up by the medical men to educate the newspapers.

Dr. Wetherill of Denver called attention to the use of the instrument called by the pyrographers a blender, which emitted a jet of hot benzine vapor through the platinum point of the Paquelin cautery; this vapor penetrated further than the cautery, and he had found it very useful.

Dr. Bernard Cohen of Buffalo said that the New York State cancer laboratory had shown cancer to be infectious in the occurrence of a distinct cancer belt through the country, and by the cage infection of mice. He thought that the step taken by their health authorities in recording all the houses in which cancer patients died was a step in the line of prevention of cancer and grouping it with the infectious diseases.

Dr. Boldt, in closing, said that the whole point of his paper would be lost if no committee were appointed to consider the campaign of education aiming at the early diagnosis of cancer.

Dr. Dorsett moved, and the motion was carried, that the chair appoint a committee to recommend Dr. Boldt's suggestion to the House of Delegates.

Some Minor Gynecological Matters That Are Often Overlooked.—Dr. I. S. Stone of Washington, D. C., considered the minor cases that were so frequently neglected in the haste to apply surgical treatment to every form of genital disease. Their appreciation required a careful examination and consideration of many general conditions, instead of the common practise of treating every discharge as a gonorrhea, or at least an infection, merely because the parts are red and swollen. Many of these cases represent a neuritis, or hyperasthesia, part of a neurasthenia, in which local applications are useless and an operation can only do harm. Frequently an urethral caruncle is due to an associated neuritis.

Tetanus Developing Twelve Days After Shortening of the Round Ligaments.—Dr. Reuben Peterson of Ann Arbor presented a report of a case occurring in his service in a girl of nineteen years. He did a curettage and round ligament operation, the abdomen not being opened. He used iodine catgut, which was removed from the apparently clean wounds on the tenth day. Two days later there appeared rigidity of the jaws, which was not considered serious until eight days later, when the back and neck also became rigid. The esophagus and face were normal. Antitetanic serum was given. A small blister was found on one end of the wound. Culture from it showed only staphylococcus. The only change in technique from that in use for years had been the introduction a week before of iodine catgut. This had been tested before, and was tested later, and never found infected. In 150 cases collected by the author some showed the catgut to have been the cause of the infection. In six cases silk only had been used. He drew attention to the marked resistsance of the tetanus spores to sterilization measures, surviving boiling for an hour. The treatment by serum was good for the condition in the blood, but had no effect after the poison had involved the nerves. The mortality of the series was over 80 per cent.

Dr. Dorsett of St. Louis said that the size of the gut as well as the material had to be considered. In some cases occurring in his experience he had shown the infection to be from kangaroo tendon, which is larger than catgut.

Dr. Waldo of New York said that he had had four cases in which he had used large size catgut for ligature of the adnexa. Two other cases operated on at the same time had been free from the infection. He had given chloroform to control the convulsions and serum, but three of the patients had died. He considered the serum useless after the symptoms appeared.

Dr. Hutchins of Ann Arbor said that the surgeons were too apt to blame the catgut for these infections. The catgut might be the cause of the infection in some cases, but was not in all. He did not think that Dr. Peterson's catgut had been efficiently tested, as no anerobic cultures had been made. Salads and green garden foods were very liable to contain tetanus spores, which, through the feces, were very apt to contaminate hemorrhoidal and perineal operations.

Dr. Frederick of Buffalo reported a case of myomectomy that developed tetanus on the sixteenth day. He had operated on three other patients on the same day with the same technique, and had no other infections. In this case the woman had had an attack of acute indigestion five days before. She was very fond of salads and raw fruits. Dr. Frederick in this case suspected the intestine as the source of infection rather than the operation.

The Stem Pessary in Dysmenorrhea, Amenorrhea, and Sterility.—Dr. J. H. Carstens of Detroit entered a plea for the use of the stem pessary in appropriate cases. In the case of infantile uteri he thought that the uterus could often be developed by the insertion of the stem pessary or any foreign body. In premature atrophy from disuse the wearing of the stem for a year or two was a benefit. He had also found it helpful in dysmenorrhea, intermenstrual pain, some displacements, and sterility due to internal os stenosis. Its use was contraindicated whenever any septic or inflammatory conditions were present in the pelvis. He dilated the cervix under anesthesia, introduced a pessary slightly shorter than the uterine cavity, swabbed out the cavity with phenol, and introduced the pessary. He gave carbolized douches for two days and then let the patient get up. He left the pessary in position for months at a time.

Dr. Howard Kelly of Baltimore said that he never used intrauterine applications or pessaries.

Dr. Jack of Illinois said that he had found the stem pessary very useful. It had brought mental wrecks up to a standard of active life by saving nerve irritation.

Dr. Benjamin of Minneapolis used the other forms of pessary with good results. He thought that keeping the cervix open might lead to pregnancy, but that the stem pessary should not be used indiscriminately.

Resolution Against Abortion.—A resolution protesting against abortion for social convenience was introduced by Dr. Kelly and referred to the House of Delegates.

Conditions Simulating Early Tubal Pregnancy.—Dr. H. S. Crossen of St. Louis recounted a number of conditions that gave either a painful mass in the region of the tube or shock and collapse from some abdominal condition as the main features. Special stress was laid on the atypical cases of salpingitis which simulated the rupture of a tubal pregnancy. The author thought that gonorrheal pyosalpinx after the acute symptoms were past might lie dormant for years and be tolerated like a foreign body. Then such a tube might give rise to acute exacerbations of symptoms simulating tubal pregnancy in the increased size of abdomen and breasts missed menstruation, and then the onset of the acute pelvic symptoms associated with a mass in the adnexa. The cause of the skipping of the menstrual period was not known, but such a lapse might be the cause of the exacerbation of the symptoms in the old tubal condition. Again, acute gonorrhea might extend rapidly

through vagina and uterus and involve the tubes without giving symptoms in the other organs, and then give rise to the suspicion of tubal pregnancy. The writer also noted the similarity between tubal pregnancy and early miscarriage associated with a mild salpingitis, a uterine pregnancy, an unsuspected pelvic tumor, ovarian or tubal hemorrhage from other causes, gastritis, perforating appendicitis, with collapse sufficient to simulate internal hemorrhage, fulminating pelvic edema, and other conditions.

Extrauterine Pregnancy, with Especial Reference to the Proper Operative Period After Tubal Rupture.—Dr. L. G. Bowers of Dayton considered the diagnosis, causes, and primary location of the ovum and the course in the unoperated case leading to hemorrhage, death of the fetus, absorption, mummification, etc. As to the time of operation, the author thought that immediate operation after rupture was not as safe as delay until the period of reaction. He said that active hemorrhage was rarely found at the time of operation, and the early operation gave additional shock. He considered early diagnosis important and early operation the choice if the tube was not yet ruptured or no shock after the rupture. In the shock condition it was preferable to wait for a while, not over forty-eight hours.

SECTION ON SURGERY AND ANATOMY.

Thursday, June 10—Third Day.

Relation of Ether to Immunity.—Dr. E. A. Graham of Chicago read this paper. He demonstrated by charts that while the phagocytic power of both human and rabbit blood was reduced by ether, the administration of fats appeared very definitely to counteract this depression.

Etiology and Pathology of Joint Infections.—Dr. John B. Murphy of Chicago read this paper. He considered that arthroplasty had served a very useful purpose and although perhaps not yet completed, had at least rendered useful a few hitherto useless joints. He described in detail his experiments with the joints of dogs and stated that the final results of this work demonstrated positively the importance of the integrity of the synovial membrane. It effectually prevented either infection or severe reaction from irritants injected into the joint, but if itself injured, its protecting influence failed and the joints would be destroyed. If ten days were allowed to elapse between the time of injury of the synovial membrane and the introduction of the germ, its protecting power would seem to have been reestablished. Two per cent. formalin in glycerin was recommended as an injection medium after aspiration and removal of exudate. This tended to produce an artificial immunity. Ankylosis would in the future not be striven for as it had been in the past, but rather the restoration of proper joint motion. The inflammatory products, it should be remembered, must never be left in the joint. It was the pressure followed by local anemia which did the damage. Further pressure was undoubtedly produced by a muscular contraction, and as this rubbed the edges of the articular surfaces together, it was to be avoided by proper extension.

Arthritis Deformans.—Dr. E. H. Nichols of Boston read this paper. Until the present time great confusion had arisen owing to the fact that differentiation and classification of these joints had not been made according to natural pathological sequence and serially, but rather arbitrarily and in a disconnected manner. If the subject was studied broadly, it would be noticed that there were two types of joints, first the proliferative, which began in the synovial membrane; and the second, the degenerative, which took its origin in the cartilage proper. These two types did not represent separate diseases; there were not two types of arthritis deformans. The degenerative usually began at right angles to the joint. There was a localized softening, while in the opposite bone, there occurred immediately a corresponding outgrowth. Eburnation took place and Heberden's nodes resulted. They were not periostal outgrowths. True ankylosis did not occur in this type, the loss of motion being due to deformity. This type of joint gave papillomata—the so-called fungus—rice bodies, and joint mice. In brief these two types corresponded to more than twenty diseases. In the synovial form, there was overgrowth with bony ankylosis. In the degenerative or cartilaginous form, there was ankylosis only by deformity and production of loose foreign bodies in the joint. Clinically, very few joints should be permanently opened. In those very hot and very painful joints where the suffering was intense, he had frequently obtained good results by opening, irrigating with very hot salt solution, and closing at once accurately. On account of the so-called faulty metabolism being undoubtedly at the root of the process, intestinal hygiene was very important in the general treatment.

Dr. Bevan of Chicago, in opening the discussion, said that he had great hopes for the future of arthroplasty and described the technique which he had employed successfully and which differed somewhat from Murphy's. He regarded Dr. Nichols' paper of exceeding importance and a very promising contribution as a basis for future surgical intervention in arthritis deformans.

Dr. Moore of Minneapolis said that the last word on joints had not yet been written; that the orthopedic surgeon was still doing too much of the old fashioned let-alone work.

Dr. Nichols, in closing, said that the time of election to open a joint was upon the tenth or twelfth day from the receipt of the injury. At that time the maximum protection had developed, owing in part, no doubt, to granulation in tissue formation.

The Conservative Treatment of Sarcoma of the Long Bones.—Dr. W. B. Coley of New York read this paper, in which he said that myoloid or giant cell sarcoma in long bones had been shown to be but little less fatal than the periosteal form. He urged the importance of the *x*-ray for diagnosis and the judicious use of toxins combined with surgical procedure.

Dr. Joseph Bloodgood of Baltimore, in opening the discussion, said that it did sometimes look as though the toxins did some good, although it should not be forgotten that each and every form of sarcoma reported as having been cured by the toxins had also been cured without them. He disagreed with Coley in holding that the giant cell sarcoma was a relatively benign structure. He believed that exploratory incision was necessary for diagnosis; that amputation was not indicated save when the growth was so large that the limb would be of no functional value.

Dr. Arthur Bevan of Chicago had used the toxins in about forty cases, but while large masses of tumors had unquestionably disappeared, he had as yet unfortunately never seen a cure. He believed, however, that the toxins were indicated in inoperable cases.

The Transperitoneal Operation for the Removal of Bladder Neoplasms.—Dr. E. S. Judd of Rochester, Minn., read this paper. He said that specimens of tumor could always be obtained by a cystoscopic method. Heretofore the results following operation in quite a large class of bladder tumors had been very discouraging. Furthermore, it was now thoroughly accepted that all papillomata would eventually become malignant. Fortunately, however, the extension to the glands was always late. Inasmuch as the majority of these tumors were in the region of the trigone, which became necessary to develop a technique which should lay bare the entire field of operation, and prevent further working in the dark. Except in complicated cases, he no longer drained. He reported

fifteen cases with one death; nine of these were malignant papillomata. In size the tumors varied from a marble to a growth occupying most of the cavity of the bladder.

A Radical Operation for Certain Forms of Hydrocele.—Dr. Willard Bartlett of St. Louis read this paper. He said there was nothing very difficult about the removal of the hydrocele sac, if the excision was commenced at the spermatic cord where the tissue was mostly areolar, and one did not in this way remove the entire thickness of the tunica vaginalis. It was essentially similar to the removal of the sac in hernia and was in the same sense radical. It formed a part of the guaranty against recurrence.

Dilatation Treatment of Urethral Stricture.—Dr. V. C. Pedersen of New York read this paper. He said it was axiomatic that cutting operations were necessary only when drainage was required. Anuria was one of the greatest dangers. He was in the habit of filling the bladder with a warm antiseptic solution after instrumentation. This served the double purpose of quieting irritability and caring for any possible infection. He exhibited a set of new irrigating sounds through which this irrigation might be accomplished, thus avoiding double instrumentation. Flexible instruments were in no way equal to the rigid, because among other things they early developed microscopic cracks, which rendered them difficult of sterilization.

Dr. L. Davis of Boston said that he had operated in three cases of bladder neoplasms very satisfactorily through the transperitoneal route. He gave the indications for and against, and stated that splitting the posterior walls of the bladder was not accompanied by any danger and did give most excellent technical opportunities. He advised, however, post operative drainage and also stated that it was important to locate the exact position of the growth by microscopic examination, because after bladder section the tumors were apt to flatten out.

Dr. Watts of Virginia advised the splitting of the scrotum and the excision of extensive strictures. The result in a number of cases had been excellent; there was no difficulty in reuniting the cut ends even after the removal of several centimeters and he believed operation had not been employed frequently enough.

Some Therapeutic Possibilities of Cholecystostomy.—Dr. L. L. McArthur of Chicago described a most ingenious operation which he said bore certain relation to the use of the appendix for irrigation purposes. He simply placed an irrigating tube in the fundus of the gall-bladder in such manner that when it was withdrawn the serous surfaces would coapt and unite. Recognizing that the duodenum was unquestionably the center of many so-called cholemic disturbances associated with jaundice and kindred symptoms, he had decided to irrigate the duodenum through the bileducts. In this way he had instilled often as much as 5,000 cubic centimeters and was certain that he had in this way reduced the time of recovery to one-half, and had cleared up jaundice in a much shorter time than by any other therapeutic agent. He had usually allowed the water to drop in, but on certain occasions had found it expedient to allow it to run so fast that it had swept into the stomach and so on out through the mouth. It was an excellent method of stimulating renal action in all diseases of the upper quadrant of the abdomen and seemed to him safer than duodenostomy, which had been suggested.

Dr. A. F. Jonas of Omaha, Nebraska, said that it was generally conceded that drainage was the most important factor affecting the post operative or of the general therapy of the disease of the upper right side of the abdomen, and he considered Dr. McArthur's technique a most valuable contribution.

Dr. J. W. D. Maury of New York said that it was timely and significant to notice that the experimental studies which had been progressing along the same line as the clinical and operative work and which had approached the problem from an entirely different standpoint, had come together so conclusively and so unanimously. From the results of his experimental studies on intestinal obstruction and from the embryological unity of the parts, there seemed no doubt that the main source of the disturbing elements was to be found in the duodenum. He had been in the habit of irrigating the duodenum in animals through a duodenostomy, but Dr. McArthur's operation seemed safer and altogether better; the important point was to thoroughly flush the duodenum.

Principles Underlying the Surgery of the Spleen.—Dr. W. J. Mayo of Rochester, Minn., read this paper. Up to the present time, splenic surgery had necessarily been destructive. The only known nervous supply was through the sympathetic system; this showed a very ancient origin of the organ, for it probably antedated the central nervous system. The internal secretion, while undoubtedly present was not important, for the removal of the organ was not followed by destruction or secretory changes. Physiologically it was concerned with blood formation, with the destruction of degenerated red blood corpuscles; with the filtration of microorganisms and with aiding the liver in the metabolism of certain food. At operations where he had had an opportunity to study the actual size and position of the spleen, he had been struck with the great difficulty of learning anything important as to its physical properties by ordinary examination, until after it had passed below the free border of the ribs. The two operations which suggested themselves from a study of clinical function were naturally partial splenectomy and ligation of the blood supply. It was known that the spleen was greatly increased in primary anemia. He described the operation of removal and stated that one interesting observation was the presence of long bone pain which persisted for several months after splenectomy.

Dr. A. J. Ochsner of Chicago, in opening the discussion, said that the field of splenic surgery had been very circumscribed, because the pathology of the organ was but little known. He concluded that if there were no splenic leukemia, that is, if the white count were beneath 50,000, and if proper attention were given to details, splenectomy was a very safe operation. If the white count was higher than 50,000, one might look for a fatal hemorrhage.

Treatment of the Appendix Stump.—Dr. Van Buren Knott of Sioux City, Iowa, said that speed was of such great importance and this operation had to be done so often by inexperienced men far from hospital accommodations, that it was important a method should be generally accepted which was quick, safe, and easy. He reported 800 cases in which the stump had simply been tied off with a silk ligature and cauterized. He had had the opportunity to examine the site of the appendix some months after quite a number of operations and had uniformly found no adhesions and almost invariably no vestige of the stump.

Consideration of the Mortality in Appendicitis.—Dr Le Grand Guerry of Columbus, S. C., reported 545 appendix operations with a mortality of two. Of these 240 were chronic cases in which no deaths occurred. Both deaths had occurred in the first hundred of the series. He considered that this remarkable showing was due entirely to the fact that he had been able to apply intelligently the epoch-making treatment of Ochsner. He made it a rule always to operate before the 36th hour and only in the rarest instances after that time, always starting the starvation treatment and waiting for the walling-off process to be finished. He concluded that the Ochsner treatment was a life-saving procedure and believed it to be the most important addition made to surgical therapy in the last ten years.

The Cause of Death in Acute Intestinal Obstruction and Kindred Conditions.—Dr. J. W. Draper

Maury of New York read this paper. He said that while the clinical surgeons had said a great deal about the treatment of pancreatitis, of stomach conditions, and of liver and duct lesions, they had refrained from saying anything definite about the etiology of these conditions. The treatment of all had been summed up in one word, drainage Unfortunately his experimental work was not finished, but enough had been done to convince him that death in intestinal obstruction took place, except where the lesion was situated in the lower jejunum or the ileum, from a disturbance which was purely physiological in type. There was nothing of the nature of an infection about it and the nervous system as such undoubtedly played no part in it any more than it did in the death which followed the removal of the parathyroids or of the hypophysis cerebri In fact the similarity between the death from high intestinal obstruction and that following removal of certain ductless glands was so striking clinically that Dr. Welch had been led to believe the duodenum might have an internal secretion. It was very significant that there seemed so close a clinical relationship between diseases of the pancreas, liver, and upper intestine as had been shown by Dr. McArthur. This perhaps was to be explained on the ground of their common embryological origin from the primitive foregut. This origin really made them in the adult a morphological unit and it was therefore not surprising that they should yield to the same sort of treatment, viz., irrigation of the duodenum.

Friday, June 11—Fourth Day.

Epithelioma of the Lip.—Dr. J. C. Stewart of Minneapolis read this paper. It consisted in argument for the removal of the submaxillary and cervical lymph glands, together with the lymphatics draining the growth. It became evident that instead of the V being point downward, it should be base downward. His operation consisted in (1) a skin section from angle to angle and turning down of the skin flap; (2) a turning out of all lymphatic and other glands and their removal; (3) broad removal of the growth; (4) repair. It was necessary at times to enlarge the mouth. This operation had given almost total freedom from recurrence, and there was no question in the author's mind that it would save fully 20 per cent. of the cases which now went to destruction. because of the general use of the ordinary V incision.

Method of Procedure of Mammary Neoplasms of Doubtful Nature.—Dr. W. L. Rodman of Philadelphia said that while frozen section work might not always be accurate, still it had a very definite and growing value in the hands of competent men. There was no question as to the very real danger of removing a specimen for microscopical examination and then closing the wound for several days. It left a free field for contamination through the lymphatics or blood-vessels. Removal of a piece, however, for frozen section work, which could be done in ten minutes, the wound being immediately cauterized, seemed to him to offer no such danger. It had enabled him to save the breasts of a great many women who would otherwise have been unnecessarily mutilated. The differential diagnosis between involution mastitis and carcinoma in women at the menopause was in his opinion clinically impossible.

Radical Operation in Mammary Cancer.—Dr. J. N. Jackson of Kansas City, Mo., said that since publishing an account of this method, he had made some minor changes, but he wished to impress upon his hearers that the real importance of the technique lay not nearly so much in tte providing as it almost invariably did of a sufficient flap to cover any denudation, but in the providing for the tight closure and consequent abolition of the axillary space. If the shoulder joint were tightly surrounded by the normal axillary tissues, it prevented the possibility of subsequent scar formation and limitation of usefulness of the joint

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 18, 1909.

Dr. F. P. Solley in the Chair.

An Interesting Specimen of a Heart.—Dr. C. N. B. Camac presented this specimen, which was of special interest because of the heart lesion and the condition of the liver. The patient had been under observation for seven months. He first came to the Cornell dispensary with considerable cardiac embarrassment. He had a pulsating liver, which was observed by a number of men; at no time that he was under observation was he without this expansile pulsating liver. Over the heart was heard a loud systolic murmur, which could be differentiated into two parts, one coming from the mitral orifice, the other from the tricuspid. An adherent pericardium was suspected. During the seven months the patient was bled nine times; after each bleeding his mental condition would clear up, his breathing would become better, and he would be comfortable for three or four weeks, when he again would have this cardiac distress. A question arose, did he have cirrhosis of the liver? The autopsy revealed a widening of the mitral orifice, probably the original lesion; there was a slight puckering of the margins. The tricuspid opening was of enormous size. Practically the whole circulation was carried on by the right heart. The liver, although it had received the back pressure for a period of seven months, showed no fibrosis at all. The microscopical sections showed a very slight degree of fibrosis. The particular interest in this case was the fact that the right heart practically had maintained life for a long period of time. Cirrhosis of the liver did not develop, in spite of the great back pressure. There was no adherent pericardium.

A Clinical Gasometer for Examination of Gastric Contents and Feces.—Dr. Bassler exhibited an apparatus which he used for the chemical and bacteriological examination of gastric contents and feces. The main part of the apparatus was a fermentation tube, graduated in percentages, into which was placed an Ewald test meal, or a watery suspension of feces, or the nutritive media of bouillon or a 2 per cent. dextrose in bouillon inoculated with feces. The tube was then placed in an incubator and kept there for twenty-four hours at 37° C., when the examinations were made. In the tests the total gas content was noted, the quantity of carbon dioxide present was learned by the introduction of one or two cubic centimeters of a saturated solution of sodium hydrate, after which the remaining gases were driven through an open cock and further tested in twin bottles. In the first of these was a very weak solution of neutral litmus (a control being used to note the color change), or water with small pieces of phenophthalein and methylorange papers; in the second was a solution of lead water to note the presence of sulphurated hydrogen, hydrogen and marsh gas being burned at the drawn tube outlet. For the bacteriological test in nutritive medias (in addition to the gas results), the anaërobic bacteria might be found in the closed upright, and the aërobic in the open bulb. The fluid contents of the tube, both in the chemical and bacteriological tests, were subsequently examined in the usual laboratory ways for indol, uroresin, butyric acid, reaction, and the solid food contents. The instrument was simple, easy to handle, inexpensive, and a practical one for clinical purposes bringing within easy means of observation the important fermentative, putrefactive, and bacteriological

conditions of the stomach and intestine. By its use the true fermentative conditions of the stomach and bowels could be distinguished from the purely neurotic, a diagnoses of those gastric ulcers that did not give clinical symptoms was occasionally possible; the stagnant conditions of the stomach could often be separated into the simple atonic and the secondary atonic (pyloric stenosis) into those due to malignant disease or the benign conditions; the results from the Schmidt diets were more accurately noted, and the fermentative and putrefactive conditions of the intestine, and the class and kinds of bacteria most prevalent were easy to diagnose.

Demonstration of a Sphygmomanometer.—Dr J. Rudish presented this instrument (to be published later).

A Clinical Study of Crystalline Strophanthin.—Dr Harold C. Bailey said that since the introduction of this agent by Fraser, strophanthus had held a reputation as a heart stimulant second only to digitalis, but the variable clinical results obtained had been the cause of much discussion. Until recently it had been used by the mouth almost exclusively in therapeutics, but when employed by intravenous injection the results had been more nearly in accord with its pharmacological action. Experiments still in progress seemed to show that the absorption of this drug from the gastrointestinal tract was very uncertain. After an extensive study of its toxic action on animals in the laboratory of pharmacology of Cornell University it was investigated clinically in Bellevue Hospital, and the results of these investigations formed the subject of the paper. The crystalline strophanthin was dissolved in four thousand times its weight of normal saline, which was then sterilized by boiling and placed in serum tubes which were sealed in the flame. In the first series of twenty cases, with three exceptions, daily doses of from three-tenths to five-tenths of a milligram were given by deep muscular injection and the medication in many instances extended over a period of several days. All cases of this group showed signs of loss of compensation and were patients to whom digitalis would ordinarily have been given. It was found that a daily dose of one-half milligram of crystalline strophanthin caused some general improvement in the pulse, a lessening of the dyspnea, and at times some increase in the amount of urine. Sphygmographic tracings were not taken in these cases and the results in most instances were not at all striking. They did not feel convinced that the results obtained were not due, in part at least, to rest in bed, freedom from work and worry, and to the hospital régime. Owing to the entirely unsatisfactory results obtained in the first series of experiments, it was decided to increase the dose somewhat when necessary in the second series. There were twenty-seven cases in the second series, and they were classified as follows: Four cases of mitral disease, eight cases of mitral and tricuspid disease, four cases of aortic regurgitation, five of interstitial myocarditis with valvular lesions, three with interstitial myocarditis without valvular lesions, three with valvular disease accompanied by marked nephritis. With six exceptions these patients had an extreme degree of cardiac insufficiency with marked dilatation. The medication was controlled by a study of the tracings made by a Jacquet sphygmocardiograph and with numerous blood pressure readings from a Stanton apparatus. Dr. Bailey reported several cases in detail and illustrated by means of lantern slides the pulse and other tracings. In conclusion he stated most emphatically that he did not advise the daily dose to exceed one-half a milligram of the crystalline strophanthin, as a rule, and under no circumstances should this dose be repeated in twenty-four hours except after careful study of the effects on the circulation. Crystalline strophanthin might be given intramuscularly or intravenously. It should be dissolved in normal saline solution in the proportion of 1 to 4,000 for intramuscular injections and 1 to 6,000–8,000 for intravenous. Crystalline strophanthin was a valuable cardiac stimulant when compensation was broken in chronic interstitial myocarditis, or in any form of chronic valvular disease. Crystalline strophanthin should be used in this way only in emergencies. It was not suited for continuous use, and when continued stimulation was desired digitalis should be employed.

Dr. W. Gilman Thompson believed that crystalline strophanthin was a resurrection remedy for desperate cases, those cases that were brought into the hospital *in extremis*. The effect of a single dose in these cases was simply remarkable; the patients felt better, and there was a great relief of their dyspnea and distress. He reported the case of a woman who was brought to Bellevue Hospital *in extremis*, with great dyspnea, dilated heart, etc., and with a tremendous anasarca; she had passed no urine for several days. A dose of strophanthin was given intramuscularly and in twenty-four hours she passed 153 ounces of urine. Another patient came into the hospital in a very desperate condition caused by myocarditis. Pulmonary edema was present, and the patient soon became comatose. The breathing became so stertorous that it seemed wrong to allow her to lie there and disturb the other patients. They thought it would be a good plan to remove her to another room to die. A dose of strophanthin, however, was administered, and the next day she was not only alive but convalescing and conversational; she lived two or three weeks after. Dr. Thompson said that this was a remedy that did not harm the patients if used with caution and was a valuable addition to the armamentarium.

Dr. Nathaniel Bowditch Potter said that he used strophanthin intravenously on one patient and was so scared at the results that he gave it up. The patient had a chill and nearly died. He thought that some of the preparations of digitalis used intravenously like digalin would give as good results as Dr. Bailey had had with strophanthin.

College of Physicians of Philadelphia.

At a stated meeting held May 5 Dr Solomon Solis-Cohen and Mr. Charles H. Lawall presented a communication entitled "Report of a Case of Pentosuria, with Demonstration of the Chemical Reaction and Pertosazone Crystals." The patient was an attorney actively engaged in the pursuit of his profession, but allowing himself sufficient recreation in outdoor exercise. Examination of the urine revealed at times a reduction of Fehling's solution and a precipitation of bismuth, but further tests showed that the reducing substance was pentose and not glucose. The patient exhibited no symptoms referable to any derangement of metabolism. Drs. Joseph McFarland and P. G. Weston presented a communication entitled "The Agglutination of Human and Rabbit Blood Corpuscles by Crotalus Venom." They found that there was no actual parallelism between the hemolytic and agglutinative properties of the venom, and that certain differences existed between the reactions of rabbit blood and human blood in these respects. Dr. John B. Deaver read a paper entitled "The Rational Basis for the Surgical Treatment of Indigestion." He cited several cases to show that aggravated symptoms of indigestion may be associated with disease of the appendix even in the absence of local symptoms referable to this viscus. In the same way disease of the

gall-bladder and of the pancreas, as well as adhesions about the pylorus, may give rise to symptoms of indigestion of obscure and indefinite origin. Gastric ulcer and duodenal ulcer may be present without the occurrence of hematemesis or the appearance of blood in the stools; and carcinoma of the stomach may be far advanced before its recognition with certainty becomes possible. For these reasons exploratory operation is often justifiable in cases in which symptoms of indigestion, particularly in the absence of adequate etiological factors, do not yield with reasonable readiness and promptitude to suitable medical and physical therapeutic measures. Dr. DAVID RIESMAN read a paper entitled "The Treatment of Typhoid Fever by the Murphy Method of Saline Instillation." He pointed out the usefulness of water in the management of cases of typhoid fever. It was believed that the good effects were due in part to attenuation of toxins in the circulating blood and the flushing of the kidneys as a result of the increased diuresis. Dr. Riesman had treated a number of cases of typhoid fever by means of the method of instilling saline solution into the bowel as recommended by Dr. John E. Murphy in the treatment of peritonitis. One dram of sodium chloride and one dram of calcium lactate are added to each pint of water. The solution is conveyed from a proper recepticle through a rubber tube fitted with a vaginal douche with multiple openings. The receptacle is held at a height of from 8 to 12 inches above the level of the body and the fluid is permitted to trickle into the bowel at the rate of about a pint an hour. The fluid is kept warm by surrounding the receptacle by hot water. The patient may maintain the recumbent posture and the instillation may be kept up continuously except during sleep. There is no discomfort by day, although there is some annoyance at night and sleep is disturbed. The results in the small number of cases in which the treatment has been carried out has been satisfactory and encouraging. Many gallons of water may be introduced into the system in this way.

Tracheobronchial Adenopathies in Their Relations to Chronic Pulmonary Tuberculosis in Children.—Charles Leroux, as a result of the treatment of many cases of tracheobronchial tuberculosis, states that there are two modes of origin of this condition: it may begin in the glands and extend to the lungs, or vice versa. Age is an important factor in determining its origin. Unilateral adenopathies are found in children from two to five years of age. Tuberculosis of the apex is found in children between six and ten years of age. Bilateral gland enlargement also occurs at the same ages. Cure of these glandular enlargements before the lungs have been affected is quite easy if the child is sent to live at the seashore for a considerable time. A short sojourn only produces a cessation of the process for a short period, and it recurs again. Radioscopy is very useful in making the diagnosis between tuberculosis of the glands and that of the apex. The germs enter by way of the lungs and upper respiratory tract in general. Rarely they enter from the intestines or descend from the rhinopharyngeal region.—*Archives de Médecine des Infants.*

Pancreatic Cyst in an Infant.—Telling and Dobson report a case from the Women's and Children's Hospital in Leeds of an infant, eleven months of age, brought in for a swelling of the abdomen of two months' standing. The child was in fair condition, the abdomen a little full. The stools were normal. The girth was 18¼ inches. The swelling was mainly central. There was resonance in the flanks and dulness at the umbilicus. The weight was 19¼ pounds. Two weeks later the abdomen measured 21¾ inches. One month after admission, on examination under anesthesia, a globular, firmly fixed tumor which did not move with respiration was made out. Two weeks later at operation it was found that the tumor was a cyst arising from the head of the pancreas. The cyst was drained and 1½ pints of fluid escaped. This was milky, slightly bloody, alkaline. Sp. gr. 10.25. Contained much albumin, but no sugar. No fermentation was obtained. No organism was found, but the fluid contained pus, blood, and homogeneous *débris.* The patient made an uninterrupted recovery.—*British Journal of Children's Diseases.*

THE ENZYME TREATMENT FOR CANCER —FINAL REPORT.

By WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D.,

NEW YORK.

SURGEON, NEW YORK SKIN AND CANCER HOSPITAL; HONORARY PRESIDENT, FIRST INTERNATIONAL CONGRESS ON CANCER; SECRETARY, COMMITTEE ON SCIENTIFIC RESEARCH, NEW YORK SKIN AND CANCER HOSPITAL.

In a previous communication—"Trypsin in Cancer, a Preliminary Statement," published concurrently in the *British Medical Journal* and the *New York Medical Journal*, March 2, 1907—I expressed the determination of giving to the "enzyme treatment," as outlined by Dr. John Beard of Edinburgh, a thorough, scientific test, in a sufficiently large number of cases and over a long enough period of time, to warrant some claim to finality when conclusions were drawn. It was pointed out that many months must needs elapse before such a test could be reported in full. Now, after an interim of more than two years since the "preliminary statement" was made, and full three years since I began to employ the enzyme method, it would seem that a final report may be offered which will meet the requirements of what may be called a "fair test."

No explanation need be offered to those who have read the leading medical journals, American and European, during the last four years and more for having given to this method of treating cancer the fair trial which its originator so earnestly desired.

Dr. Beard succeeded in arousing the interest of a goodly number of the members of the profession, both in Europe and America, as is shown by the fact that more than one hundred articles have been written upon the subject, and that five hundred physicians, out of more than three thousand to whom letters of inquiry were sent by me as Secretary to the Committee on Scientific Research of the New York Skin and Cancer Hospital, have employed the method. Whatever might be one's opinion concerning the theories upon which the so-called "trypsin treatment" was based, there seemed quite enough of possible value in the method to warrant its trial. Furthermore, through the overzealous influence of certain medical writers for the lay press and a few premature enthusiasts within the ranks of the profession itself, the method was heralded far and wide, and patients soon began to make the demand that it be tried in their case. Hoping that it might prove, if not the boon which it had been pronounced, at least a helpful adjuvant, and believing that it would do no material harm, we proceeded with the test, report of which is now offered.

It is but just to all concerned—to Dr. Beard, who proposed the method; to Mr. B. T. Fairchild, who so skillfully prepared and so generously supplied the materials; to the physicians and surgeons who cooperated with us; to the laboratory workers; to the bedside attendants, and to the patients themselves—to say a word concerning the difficulties involved in giving to a non-surgical method for the treatment of cancer a thorough and final test.

The New York Skin and Cancer Hospital furnished ample clinical material from which to draw a large proportion of the cases in which the method was tried. To employ it only in advanced, irremovable, and inoperable cases was simple enough, but such cases do not give a sufficient basis for a complete trial. The surgeon, who must look upon the matter not as a "pure scientist," but as a clinician and a humanitarian, cannot bring himself voluntarily to subject a patient with cancer in an early stage, when it is amenable to complete removal by surgical intervention (certain local superficial growths in the judgment of some being excepted), to experimentation with *any* non-surgical method, no matter upon what scientific basis it may be exploited. Consequently such a method may be tried in early cases only where, despite the surgeon's earnest advice, operation is positively refused by the patient. As will be seen, a number of cases of this class are on our list.

An enormous amount of time and patience and much money were necessary in following out the details of the treatment. Inasmuch as it of necessity extended over weeks and in some instances months, it was not feasible in all cases to care for the patients in the hospital, the individuals themselves not infrequently objecting to being so long away from home. Under these circumstances, when the patient could not afford the expense, it was necessary for us to furnish medical attention and employ trained nurses to administer the treatment and carry out the régime in the home after the patient's discharge from the hospital. To follow up the records in all cases from week to week and from month to month in such a manner as to render possible an accurate report of each, meant, in many instances, tracing the patient from tenement to tenement, sometimes from city to city. Innumerable obstacles were encountered at every turn. We endeavored, however, to meet these as they arose, to follow the régime outlined as closely as was feasible according to the exigencies of the individual case, and to keep as accurate data as possible in each instance. We believe we have been reasonably successful, despite the many difficulties, yet with all our care we were unable to follow some of the patients to the end, or to the present time.

In this connection I wish to extend sincere thanks for their hearty cooperation in the work to the following: Dr. Martha Wollstein, Pathologist to the New York Skin and Cancer Hospital; Dr. James Ewing, Professor of Pathology, Cornell University Medical Department; Dr. F. B. Mallory, Professor of Pathology, Harvard University Medical School; Dr. S. Elizabeth Finch, Assistant Pathologist to the

New York Skin and Cancer Hospital; Dr. F. M. Jeffries, Pathologist to the New York Polyclinic Medical School and Hospital; Dr. F. D. Jessup, of the Department of Pathology, College of Physicians and Surgeons; Dr. E. E. Smith, Pathologist to Fordham Hospital, and others, for their valuable assistance in the laboratory phases of the work; Dr. J. Douglas Malcolm, of the staff of the New York Skin and Cancer Hospital, for his assistance in administering the treatments and following up the cases after their discharge from the hospital; Dr. Loy McAfee Ingram, Statistical Secretary to the Committee on Scientific Research of the New York Skin and Cancer Hospital, for accurate collation of scientific data, and the various graduate nurses who have so carefully executed the details of the regimen in the homes of many of the patients. Especially do we wish to express our appreciation of the generosity of those who have been kind enough to contribute funds toward covering in part the necessary expense entailed in the successful conduct of the work.

The Method.—It is not necessary for the purpose of this report to review the interesting, if not generally accepted, embryological theory of the cause and development of cancer upon which Dr. Beard founded his method of treatment. The "irresponsible trophoblast" does not concern us here. Those not familiar with the theory can easily become so by reference to Dr. Beard's printed works.

Suffice it for our purpose to say, that at all times during the trial of the enzyme treatment I have been in close touch with Dr. Beard, and have followed the essentials of his method in all respects save one. When I first began to test the treatment Dr. Beard advocated its use in all cases after operation for the removal of cancer, whether primary or secondary, and in all inoperable cases. In this I readily concurred. When, however, at a later date, he modified his views, and opposed the removal of any "living cancer," declining to accept as a scientific test any case in which there had been previous operation, of course I demurred. This demand was met, however, as we have already seen, in cases where operative intervention was positively refused. We feel, therefore, that while the method has not been tried exclusively in such cases, we have been able to test it in a sufficient number to meet this requirement with justice to Dr. Beard's modified views.

In addition to the use of the enzymes, many details of management were urged by Beard. His various suggestions were incorporated by me in the directions for the "full regimen," and were employed in our test, with modifications to suit the needs of the individual case. In the reports and the table of cases which follow,* unless otherwise specified, this regimen was executed in every instance, a copy of the directions being given to each one who administered the treatment.

DIRECTIONS.

1. *Physical Examination,* accurate and complete, made upon commencement of the treatment.

2. *Records* of each case, accurately and fully taken *daily,* with *weekly* records of the condition of the urine, blood, and, if possible, blood pressure, and weight. Both subjective and objective symptoms to be carefully noted.

*The table of one hundred cases and the detailed reports of the findings in nine cases of the thirty-six in which blood examinations were made, will appear in a subsequent issue of the MEDICAL RECORD.

3. *Diet,* wholesome and nourishing, with very little salt and no acids. Large quantities of water to be taken by the patient.

4. *Exercise* moderate.

5. *Hygienic surroundings* as good as possible, with abundant fresh air.

6. *Oral Treatment:* (1) *Holadin,* 1 capsule t.i.d., one hour before meals. (2) *"Pepule" oxgall compound,* 1 or 2 pills at night, according to requirements (to give tone to the bowels).

7. *Local Treatment: Lotio Pancreatis.*—To the quantity required for a single application, add an equal volume of freshly distilled water (unless ordered to be employed undiluted) and apply freely. Use twice daily, flushing the surface carefully with boiled water previous to renewal of solvent.

8. *Hypodermatic Treatment:* (1) *Injectio Trypsini* (Special XX). Begin with ten minims daily, increasing five minims each day until some marked reaction takes place, or until two ampoules (20 minims each) are being taken each day.

(2) *Injectio Amylopsini.* When the trypsin injections have been increased to 40 minims daily injections of amylopsin are then begun on alternate days with trypsin, never on the same day. Commence with ten minims, increasing five minims each day until the maximum dose is reached, viz., 40 minims of trypsin one day and 40 minims of amylopsin the next.

Before making the injections apply ethyl chlorid to the surface to be injected (preferably over the buttocks), or inject 1/10 grain eucaine, then inject the trypsin or amylopsin into the deeper subcutaneous tissues, not into the muscles.

Note 1. The greatest care, cleanliness, and nicety in every detail must obtain.

Note 2. The doses must be regulated with careful regard to the reactions observed.

Note 3. The contents of the ampoule must be used *only when freshly opened.*

Note 4. The ferments are destroyed by antiseptics; care must be taken therefore not to render them inert by contact with such substances.

Note 5. If there is any local irritation from the injection, despite the greatest care, dilute with equal parts of distilled sterilized water before injecting, or with equal parts of sterilized normal salt solution.

Note 6. The general condition of the patient must be given careful attention. As little narcotic medication should be given as possible, tonics and predigested foods, if indicated. Elimination by bowels, kidneys and skin is of the utmost importance.

Note 7. The treatment, after well started, is said to have a definite control over pain. Over-drugging should be avoided in order that this claim may be carefully studied in relation to the cases.

Note 8. Injections of amylopsin should not be given while the patient's stomach is empty, as the tendency to nausea is increased under such circumstances.

Note 9. If irritation results from the introduction of the entire injection in one locality, this may be overcome in the following manner: Introduce the needle tip into the tissues, inject a portion of the material, withdraw slightly, introduce in another direction and inject another portion, and so on until the entire amount is inserted into the subcutaneous tissues in "puddles" at some distance from each other, but with one common point of puncture. By taking this precaution the tissues will not be overdistended, and the tendency to irritation will be

lessened. The needle should be inserted obliquely so that the material will not escape in part through the puncture point.

Abscess formation, so-called, was noted in some cases, and has been reported by a number who have employed the method. Real abscesses are due to (1) faulty technique; (2) localization of infection in cases where there is a general condition of sepsis from absorption of broken-down material; (3) from a complicating infection such as tonsilitis or la grippe. The so-called "trypsin abscess," on the other hand, has been shown by examination of the material to be not a true abscess, but unabsorbed trypsin solution with some broken-down tissue cells. After prolonged treatment the tissues in some cases fail to absorb the material which, in time, breaks down, is discharged, and a sinus is left for a while.

The Materials.—We are indebted to Mr. B. T. Fairchild for the materials employed. They consist of the following: (1) Holadin capsule, a pancreas gland extract containing all the pancreas enzymes—trypsin, amylopsin and lipase—and the milk-curdling ferment. This is given to aid digestion. (2) "Pepule" oxgall compound, which contains inspissated oxgall, extractum pancreatis, and extract of nux vomica. This gives tone to the bowel and aids in elimination. (3) Lotio pancreatis, a glycerin extract prepared directly from the fresh gland and carrying in solution the entire soluble gland constituents. This solvent of broken-down tissue is applied topically to the ulcerating surfaces. (4) Injectio trypsini, a glycerin extract of trypsin, which, according to Beard, was supposed to "kill" the cancer cells. (5) Injectio amylopsini, a glycerin extract of amylopsin, which was thought to "digest" the dead cancer cells.

The first pancreas injections were made of a proteolytic power equal to 2 per cent. of trypsin, and adopted in consequence of a strength or "percentage" of trypsin, at first extemporaneously prepared and used by Beard and others. The medium, 60 per cent. glycerin, had already been found to meet the requirements, containing the enzymes of the fresh pancreas extract in an active and sterile condition. This, however, necessitated preliminary dilution in making the injection ready for use. Gradually clinical experience warranted an increase in tryptic power, until finally this desideratum could be achieved only by a more aqueous medium, and consequent reduction to 20 per cent. glycerin. This lower content of glycerin afforded the advantage of increase of trypsin content and increase of dosage, as found in the ampoule.

The various injections of trypsin furnished for our use were identified for convenience of record as follows: "Regular," 60 per cent. glycerin, equal to 2 per cent. trypsin (dry); "Fortified," 60 per cent. glycerin, double the strength of the "regular;" "Special," 20 per cent. glycerin, double the strength of the "regular;" "Special XX," 20 per cent. glycerin, four times the strength of the "regular" (this was used in most of our cases); "Special Quadruple X," 20 per cent. glycerin, six times the strength of the "regular" (prepared especially for this test, and said at the time to be the strongest it was possible to make).

Injections of amylopsin of corresponding strengths were furnished us. The 20 per cent. glycerin amylopsin injection presents parallel advantages with the 20 per cent. trypsin injection, in increased potency, and in available volume of dosage without dilution. Thus, twenty minims of the 20 per cent. glycerin "Special" carries an enzyme potency corresponding to a sixty minim injection composed of twenty minims of 60 per cent. glycerin solution from an ampoule, with forty minims of diluent—sterilized water.

Having noted the strengths of the injections, it will be seen from the cases detailed later, how much stronger were the injections used in many of our tests than were those employed in the cases reported by a number of writers during the earlier months of the history of this method. The idea entertained by many at first, to the effect that only moderate doses of weak solutions of trypsin could be tolerated, was proved entirely erroneous in our experience. In many cases we were able to give daily two or three ampoules (twenty minims each) and in several instances 100 minims for days at the time of the "Quadruple X" solution with no untoward effects. From this it will be seen how absurd were some of the earlier claims of "cures," as well as of the strange symptoms and "terrific" results from the small doses employed.

A careful study of the blood and urine in a certain number of cases was made, under my direction and with valuable suggestions from Dr. Martha Wollstein. For the painstaking execution of this work, and the careful recording of the findings, credit is due to Dr. S. Elizabeth Finch.

Blood Examinations.—Blood examinations were made regularly over a period of ten months in a number of hospital and dispensary cases to observe what effect, if any, was produced by the enzyme treatment on any anemia present, or on the white cells of the blood. Leucocyte and differential blood counts were made once a week in the different cases, and hemoglobin tests and red blood cell counts were made as was deemed necessary. Upon placing a case on the treatment, in so far as possible, two, preferably three, blood counts were made on two or three successive days preceding the first injection; one count within twelve hours of the first injection, and then one every twenty-four or forty-eight hours for the first few days.

Blood examinations were made in thirty-seven cases, but in only nineteen did the observations extend over a period of more than four weeks, the treatment being discontinued for one cause or another, or the patient passing out from under observation.

Of the thirty-seven cases in which blood examinations were made, nine were epitheliomata and the rest carcinomata. There were no cases of sarcoma. In four cases of the thirty-seven no operation had been performed, and the cases were still in the operable stage. In one of the four, however, complications contraindicated operation. Of the remaining thirty-three, six had not been operated upon, but were inoperable when the enzyme treatment was begun. The other cases (twenty-seven) were inoperable ones, in many of which exploratory or palliative operations had been performed. Ten cases (Nos. 33, 79, 86, 87, 89, 90, 91, 93, 95 and 98) were followed throughout the entire course of their treatment by the enzyme method.

In ten cases of the thirty-seven there was an anemia of the chlorotic type. In eight of these it developed only in the last stages of the disease. The other cases showed a mild varying grade of secondary anemia. Nucleated reds, of the type of normoblasts, were rather rare. The hemoglobin in the more severe cases varied between 45 and 75 per cent.; the number of reds from 2,168,000 to 5,580,-

000 per cubic millimeter. In no test was the hemoglobin ever higher than 85 per cent. (Fleischl hemoglobinometer).

In five cases there was an improvement in the hemoglobin during the first few weeks of enzyme treatment. In Case No. 32 there was an increase from 80 to 85 per cent., and a gain of 100,000 red blood corpuscles. The hemoglobin subsequently dropped to 70 per cent., the red cells remaining about the same. In Case No. 50 there was likewise an improvement of about 5 per cent. hemoglobin during the first two months of treatment. In Case No. 44 there was a gain of 12 per cent. hemoglobin and of nearly 700,000 red cells per cubic centimeter during four weeks of treatment. In this case the treatment was begun very soon after an operation and the gain can therefore be ascribed in but small part, if at all, to the treatment. In Case No. 79 there was an improvement of about 4 per cent., which was subsequently lost. This gain was also post-operative. In Case No. 98 there was an increase of about 5 per cent., hemoglobin and an increase of 200,000 reds per cubic centimeter during the first four weeks the patient was in the hospital.

Leucocyte and differential counts were made in four enzyme cases and one control case (Nos. 79, 91, 92, 95 and 98) three times, at the same hour on three different days, before beginning the injections. In ten enzyme cases (Nos. 22, 33, 35, 36, 44, 49, 80, 86, 87, 89, 90 and 93) and two control cases (Nos. 35 and 90) leucocyte and differential counts were made once before the beginning of the treatment. In the remaining ten cases the blood examinations were begun after the patients had had the treatment for from one to thirty weeks. In a few cases which were carefully observed during the first week or two weeks of injections there was a gradual and moderate increase in the total number of leucocytes; however, in only two cases could there be said to be no other causative factor than the trypsin injections. In five cases of cancer of the breast there was no total leucocyte count over 12,500 per cubic millimeter which could not be ascribed to causes other than the cancer. In five cases of epithelioma there was no total leucocyte count over 9,500 per cubic millimeter not accountable for by necrosis, ulceration, or other complication. The counts on the cases in which there was marked ulceration and sloughing varied between 23,500 and 34,000 per cubic millimeter.

Blood smears were made in the mornings between one and one-and-a-half hours before the noon meal and at a corresponding hour in the individual cases. Cases from the Dispensary came at corresponding hours between two and three P. M. The Wright stain was used as a rule, in some instances Ehrlich's triple stain. In making the differential counts 500 cells were counted, in some instances 1,000 cells, and in three instances only 300 or 400 cells. Over 300 differential counts were made.

The following classification was followed: polymorphonuclear neutrophiles, large mononuclears and transitionals, small mononuclears (size under polymorphonuclear), eosinophiles, mast cells, and myelocytes. Under the head of small mononuclears were included the non-granular mononuclear cell with central nucleus and small amount of protoplasm, and the mononuclear cells with small eccentric nucleus and non-granular protoplasm, present in larger amount than in the above. The size of these cells so counted was under that of the polymorphonuclear cells. For purposes of charting the per cents. of large mononuclears and transitionals were averaged together.

Summary of Blood Examinations.—A relative lymphocytosis was found at some time in the course of thirteen cases out of twenty here described. In two other cases observed over a period of three months, in which counts were not quite so frequently made and not here given, there was also a relative lymphocytosis found, making the number of cases fifteen out of twenty-two. The relative lymphocytosis was present sometimes before the beginning of the trypsin treatment, while injections were being given, and after treatment was discontinued. It was found at times in the control cases. When the course of the disease was apparently held in check the lymphocytes were relatively normal, below, or very slightly increased. In those cases in which the disease was steadily progressing the small mononuclears reached the highest relative per cent., dependent in a measure, however, on the presence or absence of complications. In the presence of any complication causing high increase in the polymorphonuclear neutrophiles the small mononuclears were, as a rule, relatively low. Out of the fifteen cases above mentioned (four epitheliomata and eleven carcinomata), nine cancers were in such locality that extension by the lymphatics and glands would naturally follow. Four were pelvic and abdominal cases of cancer, in which any progressive glandular involvement was not demonstrable. One was a case of epithelioma of the lower jaw, in which the relative per cent. was quite high, but glandular involvement was not certain. In the other seven cases of the twenty-two, in all except one there was a complication present, causing a relative and absolute increase in the polymorphonuclear cells. This one case was observed only over a period of four weeks following operation.

It is desired to emphasize the presence of a relative lymphocytosis (increase of small mononuclears) found present in the course of the above cases (irrespective of treatment) in association with progressive growth of the cancer or metastatic formation, and, frequently, found present before increased growth or enlarged or new metastases were clinically demonstrable. With the exception of four cases out of the twenty that were observed over a period of from 6 weeks to 7 months, the eosinophile cells showed a steady increase in numbers while the patients were upon the trypsin injections. Upon discontinuing the injections the eosinophile cells dropped in numbers, reaching the normal average, or much below it, in about two weeks' time. This fall in numbers per cubic millimeter occurred in every instance, although the internal treatment was continued regularly. If, because of refusal on the part of the patient or because of the general condition of the patient, two or three treatments were skipped, it was apparent in the temporary decrease in the total number of eosinophiles. In no case, however, was the relative per cent. greater than twelve, although the trypsin injections were in many of the cases pushed to the limit for the individual in question. There was no eosinophilia in any of the control cases except where there was involvement of bone.

The exact etiology of this eosinophilia is speculative. One cause which is suggested is the absorption or attempted absorption of the trypsin from the subcutaneous tissues. The eosinophilia does not entirely disappear when the patient is put on amylopsin injections after discontinuing the trypsin. This is so

judged as the count falls still lower after discontinuing all injections. There were no nodules as the result of amylopsin injections. Incidentally it may be remarked that injections of amylopsin into trypsin nodules did not in any degree hasten their absorption. In cases on the internal treatment alone there was no eosinophilia observed, although it is claimed (von Leyden and Bergell) that trypsin passes into the general circulation from internal administration and may be absorbed in large amounts. In four of the cases in which there was rectal or other intestinal involvement eosinophiles were present before treatment in from three to five per cent., representing 300 to 700 per cubic millimeter. In three cases with bone involvement (not on trypsin) eosinophiles were present in from four to six per cent., representing 460 to 1,080 eosinophiles per cubic millimeter.

Urine.—In an attempt to ascertain if there was any irritating action exerted by the trypsin on the kidneys in the cases in which it was given by mouth, hypodermatically, or by other methods, ordinary urine tests were made in connection with twenty-three cases treated with trypsin. In eight cases uranalyses were made before treatment was instituted, then every day for the first week or ten days of treatment, and thereafter as was deemed advisable. In five out of this eight neither casts nor albumin were present at any time in the urine. In two out of the eight cases there was an occasional trace of albumin, hyaline and sometimes few granular casts in the urine before the injections were begun. This condition varied while the patients were on the treatment. In one instance there was a slight exacerbation in the kidney lesion following constant and rather large doses of the trypsin. In the remaining case out of the eight, the treatment was given for a week and then discontinued for a second operation, the removal of a recurrent nodule. Following this operation the patient had a slight cold, and when the uranalyses were resumed in connection with the trypsin injections, there was a small amount of albumin, finely granular and few hyaline casts present in the urine. The patient left the hospital soon after this, and while the treatment was continued for some time no uranalyses were made outside of the hospital. In this instance casts and albumin were not present before treatment or before the second operation.

In the urine of a few cases out of the other fifteen, of the twenty-three, granular, hyaline, and few pus casts, and occasionally albumin, were observed in the very last stages of the disease. With one exception they were not present at other times. In this case, an old man over ninety, with epithelioma of the ear, there were constantly present the evidences of nephritis. The treatment had been given in large doses from the beginning, and the patient had had an acute exacerbation of the nephritis. Upon resuming the trypsin injections a second time, small increasing doses were used; it was this time taken for eight weeks, when symptoms of a beginning exacerbation of the nephritis became evident.

It was desired to study the execretion of the chlorides, phosphates, and sulhpates in connection with the trypsin treatment, but owing to the difficulty of securing a sufficient number of uncomplicated cancer cases from whom 24-hour specimens of urine could be regularly obtained this was not done.

The following method was used in testing the urine for an enzyme with properties of digestion similar to trypsin (see Hedin; *Jour. of Phys.*, Vol. XXX, 1903, pp. 155-195); also Cathcart; Products of Urotryptic Digestion, Salkowski's Festschrift, 1904). Urine with a specific gravity of 1011 and under was used undiluted, while urine with a specific gravity over 1011 was diluted one-third or one-half with distilled water for the following work. To each 1000 c.c. of the urine or urine mixture was added 5 c.c. of a 3½ per cent. solution of casein in 0.25 per cent. sodium carbonate. To less amounts 750 or 500 c.c. was added, 3 or 2½ c.c. of the 3½ per cent. solution of casein. The casein after thorough mixing with the urine was precipitated by 20 per cent. acetic acid. After complete precipitation the supernatant fluid was siphoned off and the precipitate transferred to a filter and washed free of acid with distilled water. After thorough washing the casein-enzyme combination was transferred in each case to a six ounce sterile glass-stoppered bottle, which was then filled with 0.25 per cent. or 0.5 per cent. solution of sodium carbonate made with distilled water. To each bottle were added a few pieces of fibrin that had been boiled for fifteen minutes. Toluol and chloroform were then added to each bottle to prevent putrefaction. The various bottles labeled with date and name of patient were kept in the thermostat for from one to seven months, at a temperature ranging between 35 deg. and 37 deg. C.

Four cancer cases on the trypsin treatment and a control case (epileptic) were selected as suitable, and three times a week twenty-four-hour specimens of urine were heated and the casein separated out as above described. The casein combination in each case was transferred after thorough washing to a sterile six ounce bottle, filled with 0.25 per cent. sodium carbonate, and a small amount of *unboiled* fibrin added. Toluol and chloroform were added and the bottles placed in the thermostat as soon as they were finished. These digests were made over a period of three weeks. Upon examination daily there was evident a gradual dissolving of the fibrin, and at the end of six weeks the amino-acids were found present in each case. These findings led to the making of some control digests.

Two sterile six-ounce bottles were filled with 0.25 per cent. sodium carbonate made with distilled water, and to each one was added 2½ cubic centimeters of a 3½ per cent. solution of casein. Two other sterile bottles were filled with a 0.25 per cent. sodium carbonate, and 2½ cubic centimeters of a 3½ per cent. solution of casein, and a few pieces of unboiled fibrin were added to each bottle. To another series of two bottles which were filled with 0.25 per cent. sodium carbonate were added 2½ cubic centimeters of 3½ per cent. casein solution, and a few flakes of fibrin that had been boiled for fifteen minutes. To each of the above bottles were added toluol and chloroform and they were placed in the thermostat. Observed over a period of six weeks numbers I and II of the first series remained perfectly clear, a few grains of casein being demonstrable at the bottom of the bottles. Numbers I and II of the second series showed solution of the fibrin. Number I of the third series showed slight solution of the fibrin (boiled); number II of the third series showed no change in the fibrin. Upon examination for digest products (about six weeks' time) the casein was found unaltered in bottles I and II of the first series. In the second series to which unboiled fibrin had been added digestion products were demonstrable in both bottles. In number I of the third series there was some digestion; this bottle had been frequently opened and contained *very small* amounts

of the preservatives. That the bottle became contaminated was evidenced later by its odor. Bottle number II of the third series showed no digestion.

Two more digests according to series III were made about one month later than the above. In this series number IV there was no digestion. During this month and the following there were many digests made from specimens of urine from different trypsin cases and control cases, to which the boiled fibrin was added; but not until March, 1908, was there a definite series of cases followed every day for a couple of weeks.

In March two cases on the regular trypsin treatment were selected, one a case of abdominal carcinoma, the other a case of carcinoma of the base of the tongue, epiglottis and glands of the neck. Two control cases were selected, one a patient not having cancer, the other a cancer case, but not on the trypsin treatment. Twenty-four-hour specimens of urine (when possible) or single specimens were obtained from these four patients twelve out of seventeen consecutive days. The method above described was used in separating out the supposed casein-enzyme and preparing it in each instance for the thermostat. Boiled fibrin was used in the thirty-four digests made. These digests were all kept in the brood oven four months; twelve of them were afterward kept at room temperature for another three months. In eight instances out of the thirty-four there was no evidence of any digestion of the fibrin. In three more cases there was some dissolving of the fibrin, but the presence of any of the group of amino-acids could not be demonstrated. Thus there were eleven negative digests in the thirty-four. In one control case (not cancer) the results were negative five times out of seven, but positive in the other two cases. In the other control case two digests were negative. In the trypsin cases results were negative in one instance twice and in the other three times. In seven of these eleven negative digests the urines when treated were slightly alkaline from beginning ammoniacal decomposition. These urines were probably neutral or slightly alkaline when voided. In the four other negative instances all digests made on the two days these were made gave negative results. It is possible that the casein was not sufficiently well mixed with the urines to separate any enzyme present.

In the other twenty-three digests the amino-acid group was found present in each one.

The above experiments showed the presence in the urine in cases on the trypsin treatment, in non-cancerous patients, and in patients with cancer who had not been treated by trypsin, of an enzyme possessing properties of digestion similar to trypsin. This body was not found in urines in which there was beginning ammoniacal decomposition. No attempt was made to ascertain the appearance or disappearance of the body in the urine during the various stages of a cancer case, which might be of interest in connection with the known anti-tryptic action of the serum in all cases of severe anemia, and said by Brieger and Trebing (*Berliner klin. Woch.*, July 20, 1908) to be present early in all cancer cases, and to be influenced by the administration of pancreatin as shown by a remarkable fall in this anti-tryptic action of the serum.

Effect of Trypsin upon the Tissues.—In submitting sections to pathologists for examination, in all cases where the tissues were removed after the institution of the enzyme treatment, it was requested that especial attention be directed to the determination of any structural changes that might in any way be attributable to the action of trypsin. Whenever it was possible to do so specimens were taken from time to time, care being taken in every instance not to encroach upon nature's barriers. Comparative studies were thus made of the pathological tissues before beginning the enzyme treatment, at various times during its course, and in some instances after the death of the patient.

Dr. F. B. Mallory, Professor of Pathology, Harvard Medical School, who made a number of examinations, found nothing that he could in any wise attribute to the action of the trypsin.

Dr. Martha Wollstein, Pathologist to the New York Skin and Cancer Hospital, who made the largest number of examinations during the course of the test, found no tissue changes which could be ascribed to the action of the trypsin.

Dr. James Ewing, Professor of Pathology, Cornell University Medical Department, after careful study of the specimens submitted to him, made the following statement: "In several sections the central cells in many tumor masses were loosened, degenerating or necrotic, while only the outer layers of cells adherent to an infiltrated lymph space seemed to retain their vitality. In some cases of cancerous infiltration of the uterine muscle originally larger tumor cell masses appeared to have been reduced by this process to thin strands of degenerating epithelial cells, and in some rather wide areas the tumor infiltration took the form of isolated cells scattered at wide intervals. In some cases a peculiar edema and vacuolar degeneration was prominent, but this condition differed only in degree from that sometimes seen in untreated cases.

"Occasionally there was encountered a peculiar edema and granular degeneration and fragmentation of fibrous, connective, and smooth muscle tissues which I have not seen in untreated cases. In all the cases considerable portions of the growth appeared little or not at all affected by the above mentioned degenerative processes, a fact which may account for the steady clinical progress of the disease. In one or two cases there apeared to be no change whatever referable to the treatment."

Summary.—From careful clinical and laboratory observations, extending over a period of three years, the following deductions may be drawn:

(1) That the internal medication with Holadin and oxgall aids digestion and increases elimination.

(2) That lotio pancreatis applied locally clears the ulcerating surface by removing organisms, thus aiding in diminishing the absorption of their products.

(3) That aiding digestion, increasing elimination (by skin, kidneys, and bowels), and decreasing local absorption are the most important features of the treatment.

(4) That the regime by increasing resistance may in some cases decrease the rapidity of the malignant process.

(5) That control cases given injections of glycerin and water or sterile water alone, plus the regime, did as well as those on the full enzyme treatment.

(6) That injectio trypsini, in some cases, seems to cause more rapid disintegration of (to "liquify," according to Beard) cancerous tissue.

(7) That while it may accelerate the breaking down in the center of the tumor mass, the periphery is found to be actively growing, as was true of Case VII (Case I of Dr. Morton's published series).

When injected into the tumor itself this disintegration is more marked.

(8) That because of the tendency of injectio trypsini to disintegrate the tissues, it may be a direct menace to life (*a*) by eroding large blood vessels (when the disease is contiguous to these structures, as when deep in the neck or in the pelvis), thus causing death from hemorrhage; (*b*) when given in large doses, over considerable periods of time, by overwhelming the system with toxic products (tumor toxins), thus, in some cases, hastening death.

(9) That the injections are often painful, and patients many times refuse to take them.

(10) That the so-called "trypsin abscess" proved, upon examination of the material, to be unabsorbed injectio trypsini plus broken-down tissue.

(11) That when real abscesses formed they were due to faulty technique, to localization of a general sepsis resulting from the absorption of toxic products, to an accompanying sepsis of whatever origin, or to a complicating acute infection.

(12) That injectio amylopsini seems to diminish cachexia in some cases, in accordance with the claims of Beard and others.

(13) That in some cases there was no reason to believe that injectio amylopsini exerted the action claimed for it.

(14) That when amylopsin was injected directly into the indurated area left after injecting trypsin, absorption of the trypsin solution was not hastened.

(15) That 100 minims daily of the "Quadruple X" solution, the strongest made, were given in some cases with no untoward effects.

(16) That improvement in hemoglobin (5 to 12 per cent.) during the first few weeks or trypsin treatment occurs in about one-sixth of the cases examined. In only one-third of these was the increase ascribable to the trypsin alone.

(17) That a gradual and moderate increase in the number of polymorphonuclear neutrophile cells was noted during the first two weeks of the trypsin treatment in a few of the cases.

(18) That with the exception of two cases such leucocytosis as was noted was attributable to the occurrence of complications during the first two weeks of trypsin treatment.

(19) That in fifteen out of the twenty-two cases above mentioned a steady increase (6 to 12 per cent.) in the number of eosinophile cells was noted while patients were on the trypsin injections. There was no eosinophilia in the control cases, nor in the cases treated by trypsin given by the mouth.

(20) That eosinophilia occurred regularly in cases of carcinoma involving the bones or the intestines, even without the exhibition of trypsin.

(21) That the claims for eosinophilia as a test have not been substantiated in our experience.

(22) That albumin and casts were found in the urine before treatment was begun in two cases. In neither of these was the amount of albumin or the number of casts increased at any time throughout the continuation of the trypsin injections.

(23) That in severe cases in the very last stages of the disease hyaline, granular, few pus casts, and occasionally albumin, made their appearance.

(24) That in two other cases in which it was impossible to obtain specimens of urine before beginning the treatment, albumin and casts were present when the cases came under examination; and as the trypsin doses were increased the amount of albumin and the number of casts were increased.

(25) That dextrose was at no time found in any of the urine specimens examined, not even when untoward manifestations of trypsin were present and large doses of amylopsin were being given.

(26) That the series of experiments which were conducted for the purpose of ascertaining the presence or absence of an enzyme in the urine with properties of digestion similar to trypsin, showed the presence of such an enzyme body (irregularly present) in (*a*) trypsin treated cancer cases; (*b*) noncancerous untreated cases; (*c*) cancer cases which had not received the trypsin treatment.

(27) That the exact constancy of this enzyme body in the urine with reference to the treatment was not ascertained. No enzyme body was found in urines in which there was ammoniacal decomposition.

(28) That the enzyme treatment as administered in the cases herewith reported, and according to the suggestions of Dr. Beard, plus important details of regime, does not check the cancerous process.

(29) That it does not prevent metastasis.

(30) That it *does not cure cancer.*

A CONTRIBUTION TO THE STUDY OF TREMORS.

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

NEUROLOGIST, N. Y. UNIV. AND BELL CLINIC AND HAR MORIAH HOSPITAL.

The study of tremors has occupied the attention of many great investigators with a view of enabling us possibly to devise some means of relief to those afflicted ones who are rendered helpless in following their ordinary pursuits, and in whom this condition awakens a physical depression, even despondency to the extent, not infrequently, of driving them to commit suicide. No matter, then, how insignificant a contribution to the study of this affection may be, it may bring us somewhat nearer to the solution of the problem. The particular feature of my contribution is the method of producing a characteristic curve of each form of tremor.

The ground which I intend to survey is not an untrodden one, for others have attempted to obtain a characteristic curve with each form of tremor, as I found on reading the extensive literature on the subject.

Clinically speaking, a tremor is an oscillation of a part or of the whole body produced by either a flexion of a group of muscles and a subsequent extension of their antagonists, or by a simple contraction and relaxation of the same group. This process may be a rhythmic or an arrhythmic one. It may be subdued by the will or intensified by it. Furthermore, we differentiate a static and an ataxic tremor, and finally we may include involuntary and irregular or choreiform movements.

The pathology of tremors is yet obscure, but recent investigations furnish us data sufficient to warrant the task I have undertaken. Horosley and Shaefer have obtained tremors by irritating various points in the cortex, corona radiata, and spinal cord. Silige agrees with the conclusions of Louget and Sancerott that the optic thalamus is the seat of inhibition and a lesion therein will produce a tremor. Raymond, on the other hand—who, so far as the literature shows, made a very exhaustive study of the pathology of tremors—found lesions in different places producing various tremors. In post-hemiplegic tremors he found the lesion to consist in a

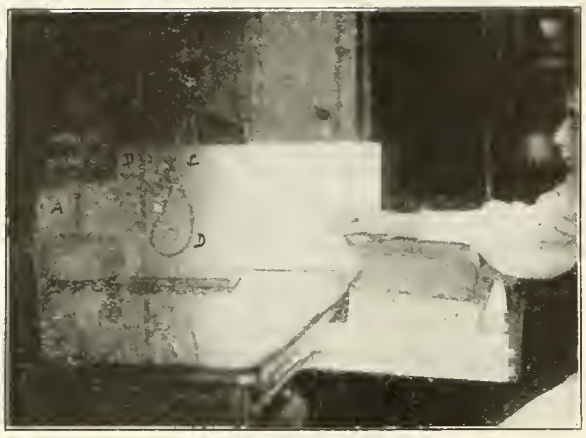

Fig. 1.—Tremograph.

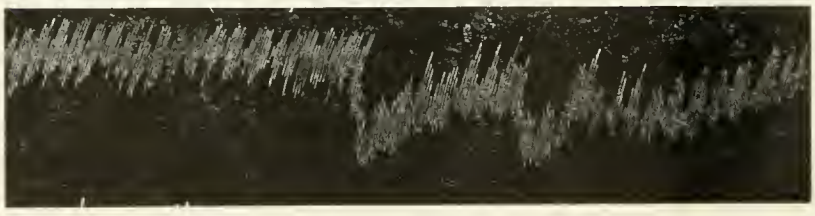

Fig. 2.—Paralysis agitans, superimposed on a post-hemiplegic tremor.

Fig. 4.—Multiple sclerosis.

Fig. 5.—Multiple sclerosis.

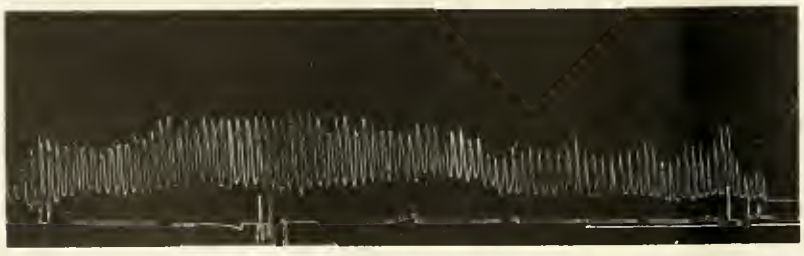

Fig. 6.—Post-hemiplegic tremor.

secondary degeneration of the lateral tracts, and the same is true of tremors accompanying cerebral atrophies. The exact site of this lesion he found to embrace an area of the lateral tracts between a horizontal line drawn through the middle of the anterior horns extending down to the posterior horns and at times even to the periphery of the cord. In multiple sclerosis and chronic myelitis he found sclerotic foci in the lateral tracts. On the other hand, in plumbism, accompanied by an ataxic tremor, lesions in the anterior horns and posterior columns were evident. It is interesting to note the lesion of hemichorea. This Raymond found in a particular fasciculus in the foot of the corona radiata. This fasciculus he describes as situated anteriorly and externally to the sensory bundle and in direct relation with the posterior part of the thalamus, covering it with its fibers. This bundle corresponds with the distribution of the posterior optic artery, which is a branch of the posterior cerebral. He bases his contention that these lesions are the cause of tremors on Charcot's explanation of tremors in lateral sclerosis. Charcot compares the spinal cord and its reflex arcs with an electrical apparatus composed of many wires, some of which are interrupted in many places. The current, then, instead of circulating freely will continue in jerks. In much the same way will probably an interruption in the lateral columns or the motor tracts of the central nervous system produce jerky instead of coordinate movements.

If, then, we clinically observe many forms of tremors and in their pathology we find that various forms of tremors are accompanied by lesions at different sites, tracings of these phenomena, or as Eshner terms them "tremograms," ought to produce characteristics peculiar to each form of this affection. And I venture to say here that for the first time in the history of these investigations I have been successful in the production of curves that give absolute characteristics of each form of tremor.

Fernet, Cramer, Debove and Boudet, Marie, Horsley and Shaefer, Eshner, and others who attempted to produce characteristic tremograms, have encountered difficulties, firstly, because of their unsuitable apparatus and, secondly, because they overlooked the fact that the part of which the record is made must be placed in a comfortable position so as not to interfere with the muscles involved and to exclude those not involved. The speed of the revolving drum has also a very important bearing upon the success of the record. Without going deeply into the details of the various apparatus used by other investigators, which have been fully described in the literature, I will at once proceed with the description of the apparatus I have devised and the manner in which I proceed to obtain a tremogram.

The apparatus consists of three parts: (*a*) a kymograph, (*c*) a tambour of the Marey type with a string attached to the lever and

fastened by a hook to a piece of rubber adhesive plaster, and (*b*) a recording tambour with a paper writing point; the two tambours are connected with a rubber tube.

The part affected is now placed in a comfortable position with the adhesive plaster attached to it. Each movement is transmitted to the lever, which causes a depression in the tambour *b*, which I shall term the receiving tambour. Here the air is compressed and the wave is transmitted to tambour *b*, which I shall term the recording tambour. This wave causes a bulging out of the membrane and a consequent lifting of the lever with its writing point. The drum of the kymograph is now revolving at a medium speed and a curve is thus registered.

I have made in all 328 tremograms including the following diseases associated with tremors: paralysis agitans, multiple sclerosis, hemiplegia, epilepsy, alcoholism, chorea, hemichorea, hysteria, cerebrospinal syphilis, dementia paralytica, and dementia præcox. The material was drawn from the salpétrière of Paris, from the divisions of Professors Raymond, Déjerine, and Voisin; from Professor Fisher's clinic at the University and Bellevue Hospital Medical College, from the Montefiore Home for Chronic Invalids, and from the division of Dr. Scratchley in the Hospital for Nervous Diseases on Blackwell's Island. I desire to thank these gentlemen for the opportunity afforded me and for their kind encouragement, and I enumerate these sources of supply for my clinical material in order to allay doubt as to the correctness of the diagnosis of the cases examined.

The characteristic feature of the tracing of paralysis agitans is the rhythmical periodicity of the curve. We notice short exacerbations of the oscillations and immediate exhaustion followed by another exacerbation. Each process occupies about two seconds, giving us a picture of a constant wave-like curve following closely the base-line with breaks at regular intervals, as shown in Figs. 2 and 3; and, no matter what the intensity of the oscillations may be, the characteristic feature of the curve will prevail.

In multiple sclerosis we get an entirely different feature, namely an arching out of the lines and a constant wandering off the base-line with breaks at irregular intervals, and curves of various sizes increased by intention, presenting a picture of segments of pointed arches (Figs. 4 and 5).

With the posthemiplegic tremors, which are intention tremors, the curve is quite different. Here the tracing also wanders off the base-line, but instead of presenting sectional arches it retains the ordinary curve for a period of five or six seconds, either to drop down toward or wander further away from the base-line, and making again a uniform curve (Fig. 6).

Fig. 7.—Chorea

Fig. 8.—Hemichorea.

Fig. 9.—Hysterical tremor.

Fig. 10.—Dementia præcox.

Fig. 11.—Dementia paralytica

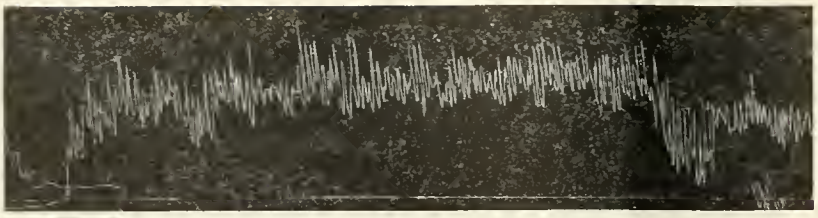

Fig. 12.—Alcoholism.

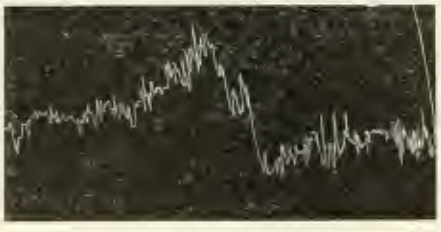

Fig. 13.—Cerebrospinal syphilis.

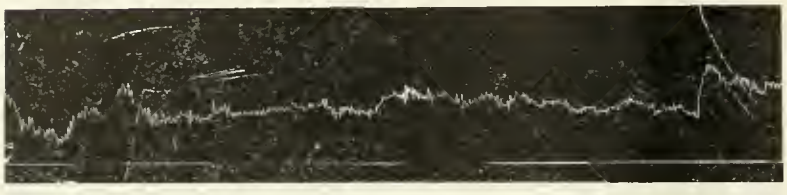

Fig. 14.—Epilepsy.

Chorea (Fig. 7) shows a uniformly characteristic feature. The curve touches the base-line at irregular intervals, giving long strokes with two or more short ones to follow them. This tremogram is to be differentiated from that of hemichorea in that one or at most two short strokes follow a long one (Fig. 8).

A characteristic curve is to be noticed in hysterical tremors. Here we have a unform and regular wave-like curve that retains its character throughout the entire course on the base-line, never wandering away from it. In connection with this tremogram I desire to mention a most interesting episode. Among the cases examined in the Salpétrière in Paris a patient with the following history, signs, and symptoms was presented to me: Mrs. Le C., 64 years old, a diabetic with an hemiplegia on the right side, 10 years duration, developed a tremor in the right hand six years ago. It looked very much like that of paralysis agitans. At the same time she had a marked ataxia, was unable to bring a cup to her lips, and had an intention tremor. I was requested to produce a tremogram with a view to determine, if possible, the nature of her affection. The patient was accordingly wheeled into the laboratory, assured by a nurse that a new treatment was to be instituted by an American doctor. She naturally manifested a great interest in the workings of my apparatus. I essayed first the right thumb, then the index finger and a regular curve as shown in Fig. 9 was obtained. Neither the characteristic Parkinson nor the post-hemiplegic tremogram is evident. The rest of the fingers showed no tremor, the spasticity of the hand gave away, she opened it freely, the ataxia disappeared, and she was able to drink from a glass as well as any normal person, and a perfect cure was effected so far as her tremor went. I saw the patient several times afterward and to all intents she was without a tremor. The result conclusively proved the diagnosis and the curve showed unmistakable characteristics of an hysterical tremor.

It is interesting to note the difference between the tracings of dementia præcox and dementia paralytica. In the former (Fig. 10) we see constant and irregular arching with oscillations from 8 to 10 per second wandering off the line, while in dementia paralytica (Fig. 11) there is no arching, but an irregular line of strokes going up and down the line and making 3 or 4 oscillations per second.

The post-epileptic tremogram is similar to that of multiple sclerosis, as shown in Fig. 14, but since I have not an opportunity to assay many cases I am not prepared to state the characteristics.

The tremogram of alcoholism is peculiarly significant (Fig. 12) inasmuch as it shows constant deviations from the base-line and at frequent intervals making long strokes, in spite of the fact that clinically it presents a constant static tremor.

Lastly, the tremor of cerebrospinal syphilis (Fig. 13) presents the same characteristics as that of multiple sclerosis. Here the etiology will have to help us rather than the tracing. While pathologically the lesion is of different nature in each affection, yet the distribution may be the same, and the tracings will of course be alike in both instances.

In conclusion, I want to say that (1) the differences between different tremors are of kind, not of degree, and every form of tremor is distinctive of a form or group of diseases.

(2) No definite relation exists between one form of tremor and any other.

(3) The frequency of movements has no bearing upon the character of the tracing.

(4) There is no material difference between the movements of the two sides of the body.

111 Second Street.

Rupture of the Receptaculum Chyli.—J. F. Dobson reports the case of a child who was run over by a hansom. Some ribs were fractured. The child was in collapse, the abdomen rigid, tender, and dull on percussion in the right loin. The abdomen contained a small quantity of blood, and a swelling was found to the outer side of the ascending colon behind the peritoneum. On incising the peritoneum a considerable quantity of thin, milky fluid escaped. The fluid came from above the vena cava. The cavity was drained and discharged freely for some days.—*The British Journal of Children's Diseases.*

GASTRIC SURGERY OF THE PRESENT DAY.*

By ROBERT C. COFFEY, M.D.,

PORTLAND, ORE.

Until within the past two years gastrointestinal surgery has made such rapid strides and so many changes that text books on gastric surgery were obsolete before they were issued. Each year the mortality rate was greatly reduced. Each year new and improved technical methods were introduced. The observer who visited the eastern clinical centers found the methods which were lauded last year discarded this year. The results which seemed good last year were not to be tolerated this year.

A few men were doing the gastric surgery of the country. During the past two years practically no changes of importance have been made in the technique of gastric surgery. Surgical principles and the finer details of technique have been worked out and fitted together so harmoniously that gastric surgeons of to-day are achieving results that seem almost as good as have been obtained in the minor abdominal surgery. In reading the statistics of 1906 and 1907, we find that the mortality was not materially lowered during the latter year over the former, and the probability is, will not be until our diagnosis is better and we are able to see the patient in time to do early and radical work.

Ten years ago gastroenterostomy and partial gastrectomy gave a mortality of from twenty to forty per cent. At the present time the same operations produce a mortality of from one to twenty per cent., depending upon the class of cases. During this stage of great mortality many reasons were sought for it. Surgeons studied the various types of operations. Various appliances were used; various stitches were devised and large series of experiments were made on animals to determine the best methods.

Some eight years ago the writer spent a considerable portion of two years in testing out results by such appliances as the Murphy button, absorbable plates and tubes, various forms of intestinal forceps and elastic ligatures. It was at that time thought dangerous to penetrate all the coats of the stomach and intestines, lest infection should follow the stitches, until Connell came forward with ample demonstration that perforation of all the coats was not dangerous, and that it was necessary in order to get good intestinal union. He thought it necessary to tie all knots on the inside, and devised a very ingenious method of doing it. Connell's persistence in demonstrating and redemonstratiug that the through and through suture was the only efficient method in gastrointestinal surgery and furthermore was not so dangerous as had been supposed, was of great service, and I think we do not exaggerate in considering Connell to be the peer of any in the development of the perfected technique of gastrointestinal surgery, notwithstanding the fact that his point of tying the last knot on the inside has proven to be of minor value and possibly an unnecessary refinement.

Senn, with his decalcified bone plates, paved the way for the Murphy button, possibly the most perfect surgical appliance ever invented. Maunsell paved the way for Connell's work, and Connell made the connecting link between all these surgeons and the modern perfected technique with the through-and-through suture and with rubber covered clamps serving the double purpose of holding back the contents of the canal and holding the two viscera near enough for the anastomosis to be made, thus combining all the good qualities in one. By the through and through suture, which was popularized by Connell, the firmer structures of the intestines are used, thus effectually preventing hemorrhage as well as leakage. I think it is not going too far to predict that no important advance will be made in the future in the technique of gastrointestinal anastomosis.

Early in the development of gastroenterostomy, someone suggested that the direct peristalsis of the intestine should be made parallel to that of the stomach at the point of union, therefore it was necessary to turn the aboral portion of the intestine toward the right. Bad results followed, regurgitation back into the stomach occurred and we had the vicious circle. After this the two limbs of the intestine above and below the point of union were united so as to short circuit the bile and pancreatic juice. This also failed to prevent the vicious circle. Then the proximal limb was cut off and closed, and the end sutured into the side of the distal segment. Even this did not prevent vicious circle. By observation at secondary operations and post mortem examinations, it was found that the vicious circle was probably due to adhesions which kinked the intestine on one side or the other of the anastomosis, or at the point of the anastomosis, thus causing the bile to pass around the duodenum to the stomach, or back through the opening made by the surgeon. About this time, Moynihan and Charles Mayo independently conceived the idea of making the loop so short that kinking could not take place, but they still turned the jejunum to the right. This was a very important step, and I had the pleasure of seeing Dr. W. J. Mayo during the week in which he changed from the old long loop operation, the last of which was done on one of Oregon's surgeons, over to the Moynihan operation. This operation was very much more successful than any of its predecessors, but a certain per cent. of the cases still had the vicious circle. Dr. Mayo, after making extensive study of the subject on the operating table, concluded that the normal direction of the jejunum after it came from behind the mesentary, was toward the left and into the left flank, so a little over two years ago he adopted the plan of making the anastomosis, using no loop, but bringing the stomach through the mesocolon at a point which would bring it in exact contact with the first part of the jejunum as it lay normally turning toward the left. This method produced a marked improvement over any other method which had been introduced. It is true that some of the English surgeons and a few prominent men of America have found some cases of regurgitation after this operation. It is barely possible, however, that they may have erred in technique by making the opening in the mesocolon too far to the right, for in order to bring the stomach and intestine in easy apposition, it is necessary to make the opening well to the left of the ligament of Treitz. In Dr. Mayo's hands this operation has been almost, if not entirely, free from regurgitation. In my own limited experience, consisting of but thirty operations by this method, the results have been entirely free from regurgitation, and comparatively free from pain. Mr. Moynihan has attacked Dr. Mayo's position, but has at the same time adopted a compromise in that, instead of turn-

*Read before the Idaho State Medical Association, 1908.

ing the jejunum to the right, as he formerly did, he now directs it downward as a rule, or to "whatever position seems suitable to the case." Admitting that Mr. Moynihan's practice is as sound as Dr. Mayo's (for on his ground he would be permitted to use the Mayo operation), there would still be no reason to question the correctness of Dr. Mayo's principles, for they are certainly in harmony with intestinal rotation as taught us in the study of embryology. While the mechanical technique of the operation in doing partial gastrectomy is not markedly different from that of Billroth's, the mortality has decreased several fold. After some years of the development of abdominal surgery it was the custom to lower the head and elevate the feet of the patient who had undergone a serious abdominal operation. Most of the patients who died, following stomach operations, died from pneumonia. After the introduction of the Fowler position, a great reduction of deaths in abdominal cases followed. Through practice in stomach cases it was found pneumonia occurred more frequently after stomach operations than other operations, which was believed to be due to the fact that absorption is much more rapid near the diaphragm, and that infection was absorbed rapidly and carried directly to the lungs, producing pneumonia. When the patient's head was elevated the infection was carried away from the diaphragm and absorption did not take place so rapidly, so this danger has been eliminated. Added to this, the use of Murphy's proctoclysis has taken away most of the duties of the stomach in the early part of the operation and has greatly increased elimination of the skin and kidneys, and, together with the great increase of technical skill which has developed in the hands of those who have prepared for this special line of work, has reduced the danger of shock. Favorable cases now nearly all get well. Fatalities in the hands of gastric surgeons are in those cases which are too far advanced to offer very much hope for permanent cure, but which give results better than one hundred per cent. of deaths, as is the result in cancer without surgical treatment. Just as the death rate following operations for appendicitis has in the past two or three years been reduced to a minimum in a given class of cases, so it has in pyosalpinx, tumors, etc. Likewise we have arrived at the stage of what might be called minimum fatality in gastric surgery, as far as operative and post-operative technique is concerned. But it is without doubt true that results will continue to improve markedly because the class of cases which we receive from the general practitioner and internist will improve by earlier and more accurate diagnosis. This is already coming true in cases of ulcer. Like all other goods things, surgery for non-malignant diseases of the stomach was unquestionably overdone a few years ago and therefore is diminishing rather than increasing. We find that while the Mayo brothers had 535 more abdominal operations in 1907 than they did in 1906, the number of operations for ulcers of the stomach was reduced from 104 in 1906 to 81 in 1907; and while the number of cases of cancer of the stomach and duodenum has increased from 77 in 1906 to 83 in 1907; cancer of the large intestine from 36 in 1906 to 41 in 1907; while the gall-bladder cases increased from 318 in 1906 to 445 in 1907. Instead of the large number of cases of ulcer there were reported 35 cases of pyloric spasm which were due to gallstones, appendicitis, or tuberculosis of the cecum.

Mayo in a recent number of the *Annals of Surgery* gives a picture of how it is possible to produce an anemic spot at the pylorus by lifting it up in the right way. These anemic spots have in the early part of gastric surgery deceived even the surgeon himself as well as the bystander. Mayo says recently, "We are inclined to look with a good deal of suspicion upon any supposed ulcer of the stomach which cannot be absolutely demonstrated not only to the operator, but to the onlooker as well."

It is a well-known fact that almost all cases of vicious circle have followed operations when there was little or no obstruction of the pylorus. Leggett and Maury did gastrojejunostomy or gastroduodenostomy on a series of dogs by the suture method and in two weeks the dogs were permitted to swallow pieces of meat in which small bullets tied to strings were imbedded. The upper end of the strings was then sutured to the pterygo maxillary ligaments. They found that the solid bodies, instead of being carried down the intestines, were returned into the stomach and in one instance the bullet passed out through the stoma; back through the pylorus, around through the stoma again, and back into the stomach. They suggest that the Murphy button might be returned in the same manner. It seems that the upper part of the intestinal tract tends to return solid bodies to the stomach for further action. On the other hand, they found that in gastroenterostomy, which was made between the stomach and ileum, the shot passed through the pylorus instead of the stoma, but the dogs so treated did not live long; first gaining, then losing, and finally, dying. So Leggett and Maury say their experience supports Blake's contentions, that gastroenterostomy should not be done except in the presence of pyloric stenosis. I would make an exception to this rule, however, as good results also follow gastroenterostomy for extensive ulcer along the lesser curvature in the majority of cases. This, however, may be due to the fact that as Cannon demonstrates in experimental work, in severe injury to the intestinal wall, the pylorus becomes closed and remains so for several hours. "It would appear," says Mayo, "that control of the pyloric sphincter is vested not only in the stomach and duodenum, but also in all the derivatives of the mid-gut, including the cecum, and that pyloric spasm may and often does originate in the attempt to prevent food entering the intestinal tract." It is probable that a well formed crater-like ulcer may produce this same spasm of the pylorus and thereby force the food out through the stoma.

In summing up conclusions as to the status of gastric surgery of the present day, we may say:

1. The operative and post-operative technique of gastric surgery is well nigh perfect and complete. Gastrointestinal anastomosis by rubber covered clamps and through and through suture as performed to-day leaves nothing to be desired. The "no-loop gastroenterostomy" gives as perfect results as any other operation in surgery. Partial gastrectomy as performed to-day is apparently mechanically perfect. Exaggerated Fowler position with Murphy's proctoclysis makes the post-operative treatment apparently complete. Modern methods of treating perforative peritonitis takes away many of the terrors of perforating gastric ulcer, if the surgeon is called early.

2. It is probable that the minimum fatality in gastric surgery has been reached, until both public and profession have been educated along this line

as they have been in the line of tuberculosis. Gastroenterostomy for obstructive ulcer in the hands of the well trained gastric surgeon should not produce a mortality to exceed two or three per cent, and in the hands of some surgeons, notably the Mayo brothers, it has been considerably less recently. Gastric ulcers of this type are nearly all cured by gastroenterostomy. Approximately two per cent of ulcers so cured develop carcinoma later. Ulcer of the stomach which produces no obstruction or which cannot be easily demonstrated, is not a surgical condition. When operated on these cases frequently develop vicious circle. Partial gastrectomy for cancer near the pylorus if done early should have an operative mortality not exceeding ten per cent. Mortality in all cases as we have them at the present day which justify an attempt at radical cure should not exceed twenty per cent. Of those diagnosed and operated on early in the disease and surviving the operation, from twenty to thirty per cent might be classed as cured according to our best statistics. Of all patients seen early enough to justify at all an attempt at radical cure and who survive the operation, approximately fifteen per cent may be classed as cures. Incurable cases, in which the pylorus is obstructed, are greatly benefited and life prolonged by gastroenterostomy, and the operative risk is small. Exploratory operation in cases which prove to be inoperable has practically no fatality, does not add greatly to discomfort of the patient, and does not prevent his going home within two or three days after the operation. A patient should have the benefit of this operation except in palpably hopeless cases.

3. Early diagnosis of Cancer is the desideratum of gastric surgery of the present day. This will only be brought about by a long period of education. The public must be instructed that a stomach trouble growing worse or beginning after the age of forty years demands the advice of a physician, for approximately twenty-five per cent of the cases are hopeless when they come to the family physician, having already used all the dyspepsia cures known. The family physician should be instructed that the stomach trouble growing worse or beginning after the age of thirty-eight or forty, not improved by dietetics and ordinary digestives in a few weeks, and especially if accompanied by loss of weight, should be recommended to someone who has facilities for thorough investigation of this class of cases. The average family practitioner is not prepared to make a diagnosis of gastric cancer until it is too late to cure it, as attested by the fact that seventy-five per cent at least of all cases are hopeless when he turns them over to the surgeon. The thoroughly trained scientific internist should be urged to see as much gastric surgery of this kind as possible in order to help to extricate him from the delusions he has developed from post-mortem training, for many of our best internists are holding on to doubtful cases, when an exploratory incision would reveal cancer.

4. No authentic cure of cancer of the stomach has ever been recorded by any other than surgical means. Therefore, the surgeon is the only man prepared to treat this condition and moreover, is best fitted to diagnosticate the condition, provided he has associated with him good reliable laboratory workers. Frequent consultation between the internist, surgeon and family physician in all obscure chronic abdominal conditions will bring about a great improvement in our surgical results in stomach diseases.

Following along the same lines set forth in these conclusions, I beg to submit one year's personal experience in gastric surgery, beginning January 18, 1907, and ending January 10, 1908, for the purpose of further setting forth the fact that patients afflicted with stomach diseases do not come to the surgeon until all other resources have been exhausted, but rather consult first the family physician and then the internist; also that the operative mortality is not necessarily great, but that the advanced stage of the cancer cases when they reach the surgeon is the serious feature.

Case I.—January 18, 1907, female, age 34. Gastric ulcer with hard cicatricial margins located on lesser curvature near oesophagus. Operation, Mayo gastroenterostomy. Symptomatic cure.

Case II.—January 20, 1907, male, age 36. Chronic gastric ulcer with history of recurring hemorrhages. Ulcer on stomach at side of pylorus. Operation, Mayo gastroenterostomy. Symptomatic cure.

Case III.—February 15, 1907, female, age 34. Decided obstruction symptoms and complete invalidism, due to prolapse of stomach. Hammock operation, suturing great omentum to abdominal wall. Greatly relieved and able to assume household duties. Had previously been treated by many physicians who had used bandages, etc.

Case IV.—March 18, 1907, male, age 44. Gastric ulcer obstructing pylorus. Mayo gastroenterostomy. Symptomatic cure.

Case V.—Female. Extreme gastroptosis with tuberculous ulcer of small intestine. Hammock operation (ill advised). No relief. Lived three months.

Case VI.—April 18, 1907, male, age 55. Exploratory operation. Gastric carcinoma of posterior wall. No relief, lived four months.

Case VII.—April, 1907, male, age 48. Cancer, with total obstruction of pylorus for six weeks' standing. Mayo gastroenterostomy for temporary drainage. Complete relief and great improvement in health. Partial gastrectomy May 10 (see case XI.). Had been previously treated for an aggravated case of dyspepsia.

Case VIII.—Male, age 52. Exploratory operation revealed carcinoma of lesser curvature based on previously existing saddle ulcer. Lived four months. Previously treated by various physicians for dyspepsia.

Case IX.—May 3, 1907, male, age 42. Complete obstruction of pylorus due to cicatricial ulcer base. Mayo gastroenterostomy. Cure.

Case X.—May 7, 1907, male, age 45. Perigastric adhesions broken up with only partial relief.

Case XI.—May 10, 1907, male, age 48. Partial gastrectomy, gastroenterostomy having been previously performed (see case VII.). Syptomatic cure, patient gaining forty pounds in six weeks. Cancer reappeared in liver four and one-half months after operation and patient died eight weeks later. Worked as contractor and builder all summer.

Case XII.—May 19, 1907, male, age 36. Marked symptoms of chronic intestinal obstruction making cathartics ineffectual. Prolapse of stomach and colon. Hammock operation. Symptomatic cure.

Case XIII.—June 26, 1908, male, age 18. Exploratory operation. Sarcoma posterior wall involving pancreas. No relief. Died one week later from hemorrhage.

Case XIV.—June 17, 1907, male, age 44. Total obstruction with vomiting for many weeks. Lost

ninety pounds. Operation for cancer of pylorus, larger than a man's fist. Partial gastrectomy. Regained sixty pounds in two months. Cancer recurred in liver three months later followed by death six weeks later. Referred by general practitioner. Previously treated for dyspepsia for many months.

Case XV.—July 10, 1907, male, age 42. Sent in for acute perforative peritonitis and diagnosed by the writer as probably appendicitis. Operation revealing perforating duodenal ulcer which was sutured and right flank was drained. Recovery complete and no further operation indicated.

Case XVI.—July, 1907, male, age 45. Extensive gastric carcinoma. Stomach drained by Mayo gastroenterostomy. Symptomatic relief followed by death five months later.

Case XVII.—July 9, 1908, female, age 22. Chronic ulcer at pylorus with recurring hemorrhages and vomiting. Mayo gastroenterostomy. Complete cure.

Case XVIII.—August 23, 1907, female, age 36. Prolapse of stomach. Hammock operation. Symptomatic cure.

Case XIX.—October 1, 1907, female, age 26. Gastric ulcer obstructing pylorus extending along lesser curvature for three inches. Mayo gastroenterostomy. Relief immediate and complete.

Case XX.—October 11, 1907, male, age 60. Carcinoma near pylorus and on lesser curvature of stomach. Mayo gastroenterostomy. Only partial symptomatic relief. Died two months later. Referred by internist after having taken treatment from various physicians for dyspepsia.

Case XXI.—October 15, 1907, female, age 52. Pyloric obstruction due to old ulcer. Mayo gastroenterostomy. Complete relief and rapid gain in weight.

Case XXII.—October 17, 1907, female, age 62. Carcinoma completely obstructing pylorus. The symptoms had existed for six months and cancer irremovable. Mayo gastroenterostomy. Symptomatic relief, and gain in weight. Death four months later.

Case XXIII.—November 8, 1907, female, age 36. Ulcer involving pylorus, of long standing. Mayo gastroenterostomy. Improved but not complete symptomatic cure.

Case XXIV.—November 12, 1907, female, age 60. Obstruction of pylorus by carcinoma. Partial gastrectomy. Recurrence in four months followed by death in two and one-half months. Had previously taken much medicine for indigestion.

Case XXV.—November 19, 1907, male, age 56. Carcinoma obstructing pylorus. Partial gastrectomy. Complete cure to date.

Case XXVI.—December 3, 1907, male, age 56. Large indurated ulcer on lesser curvature. Mayo gastroenterostomy; operation produced no apparent shock but was followed by complete suppression of urine and death two days after operation.

Case XXVII.—December 31, 1907, female, age 49. Carcinoma of stomach. Exploratory operation. No relief. Death two months later. Had had several months' treatment for indigestion.

Case XXVIII.—January 2, 1908, male, age 42. Carcinoma at pylorus and extending along lesser curvature. Partial gastrectomy. Recovery. No recurrence to date (June, 1909).

Case XXIX.—January 10, 1908, female, age 50. Carcinoma of posterior wall of stomach and involving liver, ascites. Exploratory operation. No improvement; death three weeks later. Had had much previous treatment for indigestion extending over a period of more than a year.

Summary of cases and operations:

Ulcer, 10—One death due to suppression of urine, one improved, and eight symptomatically cured.

Cancer, exploratory for inoperable cancer, 5—No operative deaths.

Cancer, gastroenterostomy, 4—No operative deaths. Life prolonged and made more comfortable for all.

Cancer, partial gastrectomy, 5—No operative deaths; three lived less than six months although comparatively comfortable, two well at time of sending to press, one fourteen and other eighteen months after operation.

Prolapse of stomach, Hammock operation—One improved, two cured, one unimproved, one perigastric adhesions slightly improved.

North Pacific Sanatorium.

THE TREATMENT OF SPECIFIC URETHRITIS (GONORRHEA) IN THE MALE.

By JAMES R. HAYDEN, M.D.,

NEW YORK.

PROFESSOR OF GENITOURINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY); ATTENDING GENITO-URINARY SURGEON, BELLEVUE HOSPITAL.

The great prevalence and gravity of specific urethritis together with the severity of its complications and sequellæ, to say nothing of the many and ever changing methods of treatment advocated for its rapid cure, are sufficient reasons for the selection of this much-discussed and important topic. Throughout the following pages the writer will consider only the treatment of urethral gonorrhea, purposely omitting that of its complications on account of the space required for their proper discussion.

For clinical purposes specific urethritis is best divided into four stages or periods, as follows: *First,* the *serous* or *prepurulent stage,* in which the patient has a slight watery discharge and in which the gonococci are free and superficially seated upon the mucous membrane of the fossa navicularis. *Second,* the *stage* of *acute suppuration,* in which the discharge is purulent, and the gonococci, having penetrated the cement substance between the epithelial cells, have passed down to the bloodvessels in the submucous layer and are deeply seated. *Third,* the *stage* of *decline,* in which the discharge and acute inflammatory symptoms are markedly decreased, and *fourth,* the *chronic stage,* in which the discharge is slight and the urine is clear and contains flakes.

From a study of the above-described stages, which are based upon the actual course of the disease, and its pathology, it may be safely stated that the successful treatment of gonorrhea depends entirely upon the stage of the disease in which the patient applies for treatment. In other words, if he is seen, as he very rarely is, in the first or serous stage, when the gonococci are superficially situated, abortive treatment may be employed, as in this period the diplococci are so situated as to be readily destroyed by local applications. If, on the other hand, the case is seen in the second, or the stage of acute suppuration, as it usually is, then it is too late to try abortive treatment, as by this time the gonococci have penetrated so deeply that they are beyond our reach, and any form of abortive treatment attempt-

ed at this time merely adds traumatism to the already intensely inflamed urethra, without even reaching the now deeply seated gonococci, and in addition it produces a more suitable soil for their growth and multiplication. Our aim, therefore, in this, the stage of acute suppuration, must be, not so much the destruction of the gonococcus, but rather the amelioration and cure of the acute inflammatory process, as a result of which the gonococci disappear.

In our attempts to annihilate the gonococcus we must not forget that we have a very acute and severe inflammatory process to deal with, which is attacking one of the most delicate and highly sensitive mucous membranes in the body, which, if overzealously treated in the acute, or suppurative, stage of this virulent process, leaves the urethra and its contiguous glandular structures, especially the prostate, in a more or less permanently damaged condition.

I shall now endeavor to outline a plan of treatment which in my hands, has given most satisfactory and permanent results, considering first the abortive method, and secondly what may be termed a conservative method.

Abortive Treatment.—If a microscopic examination of the serous secretion shows desquamated epithelial cells and free gonococci (*first stage*), then abortive treatment may be advised, and at the same time the patient informed that it is liable to failure in some cases. Unfortunately, however, the vast majority of patients do not consult a physician at this early period, as they then consider their disease to be but a trivial and transitory affair, thus losing the only opportunity to destroy the gonococci and prevent their invasion of the deeper tissues.

Technique of Abortive Treatment.—The patient having voided his urine, the meatus and glans are washed with sterile water, a small soft rubber catheter is passed into the fossa navicularis, the patient compressing the urethra firmly behind this point to prevent the backward passage of fluids: then by means of the catheter and hand syringe (Fig. 1.) the operator irrigates the fossa with warm

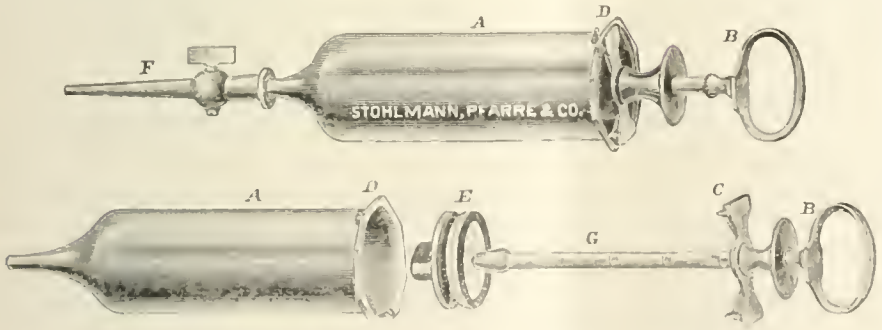

Fig. 1.—Author's irrigation syringe, with coupler and stopcock (all metal).

sterile water to free it of any remaining urine or secretion, after which it is distended with a solution of silver nitrate (10 grains to the ounce). In this manner the mucous membrane of the fossa, which is the seat of the disease at this period, is medicated with the silver solution and the gonococci situated upon its surface are destroyed. The patient is now instructed to rest as much as possible, put upon a light, nonirritating diet, both as to solids and liquids, and the urine rendered bland by still waters and alkaline mixtures. The bowels are moved freely by means of cathartic pills, and the penis and prepucial cavity kept clean by frequent immersions in hot lead water. The silver application is followed in a short time by painful urination and a purulent discharge which, if the treatment be successful, subsides in a few days, leaving the patient with a slight mucopurulent discharge, which is readily controlled by astringent injections. If, on the other hand, the treatment has failed to abort the disease, then the discharge continues, showing under the microscope gonococci and pus cells in increasing numbers, the case now presenting the clinical picture of the acute or suppurative stage, in which event all further attempts at abortive treatment should be abandoned, and the patient placed upon the "conservative" plan of treatment.

Conservative Treatment.—The presence of gonococci having been demonstrated microscopically, in the purulent urethral discharge (*second stage*), the patient's history is carefully inquired into as to the number, severity, duration and complications of previous attacks, and also the treatment employed. Each patient is given a printed list and personal instructions as to his mode of life, diet and medication, and is also told how to prevent infecting others. It is of the utmost importance that these patients be kept as quiet as possible, rest in the recumbent position being preferable, especially during the first week, when overexertion of any kind is apt to be followed by a marked increase in all of the acute inflammatory symptoms. Sexual excitement must be guarded against, as it adds greatly to the local inflammation. The diet should be light but nutritious, and contain no highly spiced or seasoned dishes, or, in fact, anything that in any way is liable to cause concentration of the urine with subsequent irritation of the urinary tract. Alcohol in all forms, as well as coffee, chocolate, cocoa, and charged or medicated water must be prohibited. To render the urine copious and bland, the patient should drink a glass of still water every hour, and take full doses of the citrate of potash, either alone or in combination with tincture of hyoscyamus.

The testicle should be worn in a snug bandage which does not impinge upon the urethral floor, thus producing injurious pressure on the inflamed canal. This point is of great practical importance when one considers the frequency of patches of infiltration, and even true stricture at the penoscrotal junction, which represents that portion of the canal pressed upon by the suspensory.

The bowels should be kept open by the use of cathartic pills, as saline purgatives are liable to produce more or less urethral irritation.

The penis should be so dressed as to allow of free drainage of the urethral pus, which at the same time must be kept from the prepucial cavity, the patient's clothing and his fingers. These requirements are fulfilled by a piece of absorbent gauze cut about four inches square, with a slit in the center through which the glans is passed until the gauze rests in the coronal sulcus, when the prepuce is drawn forward carrying the gauze before and beneath it, thus causing it to protrude beyond the prepucial orifice. If there is much inflammation in the glans and prepuce, great relief can be ob-

tained by keeping the gauze moistened with lead water. If the prepuce is too short to hold the above dressing in place, the end of the penis can be placed in a bag of absorbent gauze which is pinned to the suspensory bandage. To allay the local pain and inflammation, the penis should be immersed several times daily in a hot lead solution, which can be easily and quickly prepared by dissolving one tablet in a glass of hot water, each tablet containing 15 grains of a subacetate of lead, which is equal to about one drachm of Goulard's extract. The hot sitz bath relieves to a great extent the feeling of soreness and stiffness in the groins, penis and along the bulb.

When the disease passes into the *third stage*, or the *stage of decline*, as is indicated by a diminution and thinning of the discharge, less pain on urination, and a decrease in the redness and swelling of the meatus, it is time to begin the use of nonirritating hand injections and the antiblennorrhagics (balsamics), which latter if used at this time will give most satisfactory results. The antiblenorrhagics are liable, if continued too long, to delay the cure by overstimulation and irritation of the urethral mucous membrane, so that great care and judgment should be exercised in their use. In dispensary practice we are sometimes obliged to employ the "Lafayette mixture" on account of the price of sandal wood oil, which, if pure, is, in the writer's opinion, far superior to copaiba or cubebs, and can be given in five or ten minim capsules one hour after meals. It should never be administered in the acute stage of the disease, on account of its stimulating and even irritating effects on the mucous membrane. Should the sandal oil produce gastrointestinal irritation, or renal congestion, the quantity must be reduced, or the drug suspended for a time, and the urine examined for casts and albumen.

As a general rule, hand injections can be begun on about the seventh to the fourteenth day of the attack, depending entirely upon the amount and degree of local inflammation in each individual case. The patient must be shown how to inject his urethra in a gentle manner, the surgeon always impressing upon him the danger of forcibly injecting or overdistending the inflamed canal, and also warning him not to retain the fluid for any length of time by compressing the meatus. The solution should be warm and thrown in slowly until there is a feeling of uneasiness or beginning discomfort, when it is allowed to escape. The injections are taken three or four times in twenty-four hours, beginning with warm lead water, boric acid, or normal salt solution, which in a few days is changed to weak solutions of zinc, alum or lead, either alone or in combination, or if preferable, weak injections of permanganate of potash, which latter preparation, although of great value in the subacute stage of gonorrhea, is in the writer's opinion absolutely contraindicated in the stage of acute suppuration.

Having lessened the discharge by the use of the hand injections, great benefit will now be derived from the daily use of warm and soothing irrigations thrown into the bulb of the urethra in the following manner. The patient having urinated, the surgeon passes a small soft rubber catheter into the bulb, and injects from four to eight ounces of a warm medicated fluid slowly and gently by means of a hand syringe (Fig. 1). In this manner the solution medicates the entire anterior portion of the canal from behind forward. We should begin the irrigation treatment with warm solutions of lead water, or boric acid, and later, mild solutions of zinc, alum, permanganate of potash, and finally silver nitrate, which latter preparation brings the case to a speedy and satisfactory termination by causing absorption of the submucous exudate, and also a restoration of the damaged mucosa.

In using irrigations of nitrate of silver in the anterior urethra, it is best to begin with about 1-16,000, and increase the strength slowly and gradually up to 1-4,000, or even higher, according to the results obtained, which can be readily noted by the patient's symptoms and sensations, and also by the condition of the urine, which should be examined prior to each treatment. When, as a result of the irrigations the pus disappears and nothing but flakes and tissue elements remain in the otherwise clear urine (*fourth stage*), then it is time to stop the irrigations and substitute for them instillations, which consist of a few drops of a concentrated silver nitrate solution, thrown into the bulb by means of a small soft rubber catheter and instillation syringe (Fig. 2).

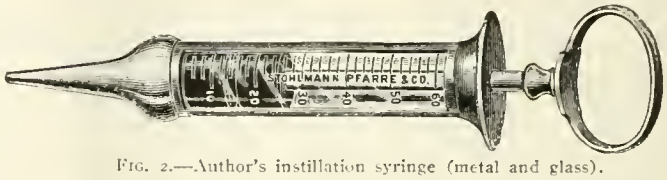

Fig. 2.—Author's instillation syringe (metal and glass).

Instillations should be given about every second to fifth day, depending upon the results obtained and the strength of the solution employed, which as a general rule is about 1-8,000 at the beginning, and finally increased up to 1-500 or even higher in rebellious cases. As a result of the instillations the flakes will be seen to grow lighter and smaller from day to day and finally disappear, so that the patient passes a normal morning urine.

If during the course of an acute anterior gonorrhea, the inflammatory process passes beyond the compressor muscle, as it frequently does, and invades the deep urethra, as is shown by a diminution of discharge, increased frequency in urination, more or less vesical tenesmus, and perhaps terminal hematuria, then we know that our patient has developed an *acute posterior gonorrhea*, the treatment for which is as follows: The patient is kept very quiet, or better still, put to bed and kept there until the acuteness of the attack subsides, as it usually does in a few days. The diet should be the same as that outlined for an acute anterior gonorrhea. All local treatment of the urethra is stopped, as in every case of posterior urethritis there is an infection of the prostate gland (prostatitis), in which condition any form of local urethral treatment is exceedingly harmful. If the patient has been taking the antiblenorrhagics, these remedies must be stopped temporarily and replaced by suitable alkaline mixtures with the addition of triticum repens and uva ursi. Still water is taken in moderation. Hot water bags over the bladder and on the perineum give much relief, as does also the hot sitz bath and especially rectal irrigations of normal salt solution at a temperature of 118° F. These irrigations are given by means of the fountain syringe and two soft rubber tubes (Fig. 3) morning and evening, using four quarts at each sitting. In this manner the prostate, deep urethra, and in fact all of the structures about the vesical neck are brought in direct contact with the hot saline solution, which soothes the inflamma-

tion and congestion, thus lessening vesical tenesmus, pain and compressor spasm. Should the above measures fail to control the acute inflammatory symptoms, we are then compelled to resort to the guarded use of sedative suppositories.

In all cases of acute posterior gonorrhea, but especially in severe ones, the surgeon should make frequent rectal examinations of the prostate and seminal vesicles, in order to be prepared to treat efficiently and promptly any pus formation that may occur in or about these structures. This point is of paramount importance, and should always be borne in mind, especially when the patient runs a high temperature, and has marked difficulty in urination. From a large number of rectal examinations, made during the course of acute posterior gonorrhea, I am firmly convinced that the prostate is involved to a greater or less degree in the vast majority, if not in all of the cases, whereas the seminal vesicles are quite exceptionally attacked. There are some cases of acute posterior urethritis which, in spite of rest, local heat, and internal medication, show no improvement, and the acute symptoms continue unabated for days. In these cases much benefit will be derived from retrojections of warm boric acid solution thrown into the deep urethra and bladder by means of a small rubber or silk catheter and hand syringe.

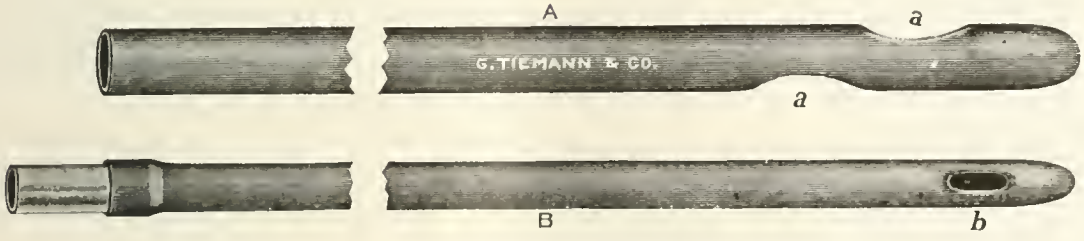

Fig. 3.—Author's rectal irrigating tube.

When the acute symptoms subside, the patient is allowed to be up and about, and the urethra treated locally in the following manner: The patient having voided his urine, lies down with head and shoulders comfortably elevated and muscles relaxed. A soft rubber catheter is passed beyond the compressor muscle and the residual urine is drawn and measured. In some rare cases it may be found impossible to pass the soft catheter beyond the muscle, and for these cases we should substitute a small woven silk instrument which, having more rigidity, passes with ease. The especially constructed metal instruments or "drop catheters," should, in the writer's opinion, never be employed, on account of the traumatism they are likely to produce, even in trained hands. If the surgeon fails to enter the deep urethra with soft rubber or woven catheters, it is proof positive that he is either unskilful, or that the parts are in a far too sensitive condition for any kind of local medication. The much talked of spasm of the compressor urethræ muscle is, as a rule, caused by rough or rapid instrumentation, and will rarely be encountered provided the surgeon is gentle and uses soft or flexible catheters in preference to metal or rigid ones. A hand syringe is now attached to the catheter by means of a coupler (Fig. 1), and the medicated fluid thrown slowly into the prostatic urethra, from which it passes upward into the bladder; the eye of the catheter is now drawn into the bulbous portion and the entire canal irrigated as the instrument is slowly withdrawn. The patient now stands and passes the medicated fluid, which, having already acted on the deep urethra and bladder base, washes out the posterior urethra a second time, and flowing forward through the anterior portion, distends it as it rushes out, and in this manner medicates all of the diseased areas along the canal. The solutions must be warm, and increased very slowly in strength, especially the silver solution, which, if used too strong, will set up intense vesical tenesmus, which is liable to be followed by an exacerbation of the acute symptoms, and also by such complications as epididymoorchitis, urethrocystitis, and severe prostatitis, with perhaps abscess formation in the gland. The fluid should always be injected with a hand syringe, as with it we know the exact amount of fluid thrown in, the resistance offered by the bladder, and the force used; whereas if an irrigator or fountain syringe were employed, none of the above valuable information could be obtained and more or less damage might be done. The amount of fluid used at each treatment varies somewhat in different cases, my custom being to throw in about four ounces into the deep urethra and bladder and about the same amount into the bulb. Beginning with boric acid and then changing to mild solutions of zinc, alum or permanganate of potash, we endeavor to use the silver nitrate as early as possible, beginning with 1-30,000 and increasing the strength in a guarded manner up to about 1-5,000, as a result of which the patient passes a clear urine, except for a few flakes and tissue elements (*fourth or chronic stage*), which condition calls for instillations of silver nitrate given in the deep urethra and bulb, by means of the soft catheter and instillation syringe. Prostatic massage, sounds, and the endoscope are employed in the chronic stage when indicated, but overdilatation with metal "dilators" is never employed on account of the injurious traumatism it produces. Injections of antigonococcus serum have been followed by gratifying results in some cases, but a discussion of this subject will be taken up at a later date.

Having described a plan of treatment which, in the writer's opinion, is based upon the pathology and course of the disease, and one also which takes into consideration the delicacy of the urethral canal and its contiguous glandular structures, we will now consider briefly some of the so-called abortive methods, or rapid cures, the inefficiency and harmful results of which are encountered almost daily, if one may judge from a fairly large personal experience, both in private, hospital, and dispensary work.

The Janet method, which consists of irrigating the urethra and bladder with warm solutions of permanganate of potash from a considerable elevation, does cause a very rapid cessation of the purulent urethral discharge as is claimed by its advocates, but at the same time it produces a very severe exudative inflammation into the submucous connective tissue layer, which leaves the canal in a thickened, congested and irritable condition, associated with a

mucoid or watery discharge, which is at best very difficult and sometimes impossible to cure, especially in those cases where the lips of the meatus have a swollen and pouting appearance. Spasm of the compressor urethræ muscle, and even of the muscular layers of the urethra, is frequently observed following this treatment, as is also a congested and painful condition of the prostate gland, which gives rise to a sense of uneasiness just before and after urination. The dribbling of urine after each act, which is so frequently complained of, is due to a loss of elasticity of the urethral walls. The muscular spasm and irritability are sometimes so marked that it is very difficult to pass a soft catheter through the anterior portion of the canal, and well nigh impossible to get it beyond the compressor muscle, even with the greatest care and gentleness. Having seen a very large number of patients suffering from the above conditions in private, hospital, and dispensary practise, I feel thoroughly convinced that I am justified in condemning this unnecessarily harsh and severe treatment, which merely washes off the surface of the mucous membrane without any beneficial action whatsoever upon the deeply seated gonococci.

The above cited sequelæ are not to be wondered at when one considers the force and strength of the solution, rushing through and distending such an acutely inflamed and swollen canal as the urethra is, in this, the acute stage of the disease; also the injurious effects of overcoming by hydraulic pressure the delicate musculature which guards the deep urethra, and parts beyond, and also the injurious dilatation of the orifices of the glandular structures opening into the urethra.

In regard to the silver salts, or "gonococcocides," which are being extensively employed at the present time as hand injections and irrigations in all stages of the disease, and which are said to destroy the gonococci in a very short time without causing any pain or injury to the urethral mucosa, I must admit that, after a fair and impartial trial, I can see no advantage from their use, nor do I get as satisfactory and permanent results as from the conservative method above described, a method which if carefully carried out in every detail will cause a rapid absorption of the submucous exudation, together with a restoration of the urethral mucous membrane; the practical results of which are fewer cases of chronic gonorrhea, stricture of the urethra, and prostatitis, to say nothing of the avoidance of the many other unnecessary sequelæ which result from the over-zealous and too radical treatment of the acute or suppurative stage.

Having considered the treatment of the disease, the ever important question now arises: When is gonorrhea cured? In order to answer this question in an intelligent manner the surgeon must examine the patient's morning urine, passed in his presence, every other day, on several successive mornings, and if it be clear and contain microscopically neither pus nor shreds; that is, if it be perfectly normal on repeated examinations, we then know that the urethral lesions have been cured. If, on the other hand, there are shreds and flakes in the urine, which under the microscope are found to consist of pus and epithelial cells, whether they contain gonococci or not, we know that the urethral lesions are still uncured, and that the secretions from these areas may be infectious. If the shreds consist of epithelial cells alone, they of course, may not be dangerous; but even these patients must be warned not to have sexual relations, and advised to take a proper course of treatment.

In order to ascertain that there is no lurking trouble in the periurethral glands, the prostate, the seminal vesicles, or the ampullated ends of the vasa deferentia, the patient should pass all of the urine, and then have the bladder filled with warm sterile water, after which the prostate, vesicles, vasa deferentia, Cowper's glands, and the periurethral follicles are carefully examined and massaged: any material appearing at the meatus as a result of this examination is caught on slides. The patient now passes the warm sterile water which washes out any remaining secretions that have been expressed into the urethra. The centrifuged sediment in the sterile water and the secretions caught at the meatus are examined microscopically, and if the findings show the prostate or other glands to be diseased, these structures should be treated and the patient be informed as to his infectious condition. The little follicles in the integument of the penis, between the layers of the prepuce, and in the lips of the meatus (paraurethral follicles), should be carefully examined in order to ascertain that they also are free from the gonorrheal process. The so-called "beer test" is never employed as it is considered crude and unnecessary, especially when we have scientific and more dignified methods at hand. The examining physician cannot be too careful in giving his opinion on this all-important subject, and should therefore make the above examinations in a most thorough, painstaking and conscientious manner, and warn patients against sexual relations until their disease is absolutely cured.

121 West Fifty-fifth Street.

A NEW SPHYGMOMANOMETER.

By J. RUDISCH, M.D.,

NEW YORK,

ATTENDING PHYSICIAN, MOUNT SINAI HOSPITAL.

While mercury manometers have come into general use for the determination of blood pressure, several important objections may be urged against them: Either fouling of the surface of the mercury or a capillary tube that is not absolutely clean will prevent accurate registration; as the result of inertia, the mercury will rise and fall in an exaggerated wave even after the force of the pulse wave has been expended; the fine dividing lines on the capillary tube make readings difficult: such manometers are not readily portable.

The chief objections advanced against manometers depending upon a spring are the inaccuracy of these instruments and their deterioration in time. The inaccuracies encountered, however, are not inherent in the principle of the spring, but are due solely to imperfections in manufacture. The second point will be discussed later. It may be pointed out that the chronometer, an extremely delicate instrument, is based wholly upon the principle of the spring.

My instrument consists of three parts — a manometer, a cuff, and a syringe. These are all connected by heavy rubber pressure tubing through a metal T-tube. The manometer consists of a hollow curved metal spring (Fig. 1, A) from the free end of which a silk thread (B) runs to an upright revolving metal bar around which it is wound. A second metal bar bearing the indicator (c) is attached to the upper end of the upright at right angles. As the air is forced into the spring, the

increase in pressure will cause the latter to straighten, this movement being communicated to the indicator through the silk thread and upright bar. The latter will revolve in proportion to the pull exerted by the hollow spring, causing the indicator to sweep over a divided dial (Fig. 2), on which the force of

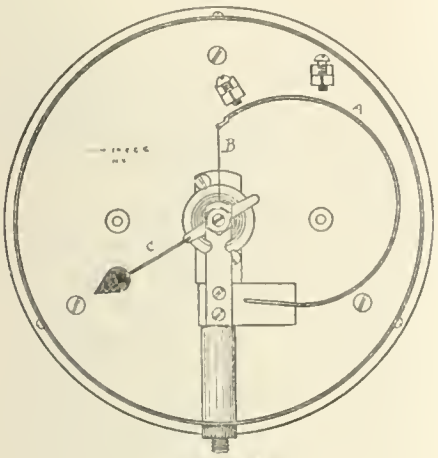

Fig. 1

the pull may be read directly in millimeters of mercury. A hairspring attached to the upright at its base and exerting its force in the opposite direction causes the indicator to return to its original position in proportion to the diminution in pressure. The dial is movable, enabling the indicator to be brought opposite the zero mark, thus counteracting variations in the position of the arrow due to thermal influences acting upon the spring.

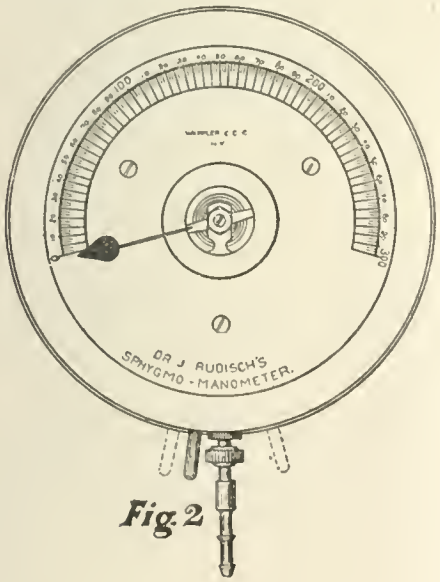

Fig. 2

The cuff is the usual 15-centimeter von Recklinghausen cuff. The metal syringe contains a two-way cock, by means of which the air pressure in the cuff and in the manometer may be readily increased or diminished at will.

To determine systolic pressure the cuff is tightly strapped about the arm. Air is forced into it and into the manometer from the syringe until the indicator shows minimal oscillations. This point is usually found to be 5 to 10 mm. higher than that at which the radial pulse is no longer palpable. To determine diastolic pressure the air is allowed to escape slowly by reversing the cock of the syringe, carefully noting the extent of the oscillations of the indicator. The point at which these oscillations are greatest will correspond to the diastolic pressure. Below this point it will be noted that the oscillations again become smaller.

The advantages of this instrument may be summed up as follows: (1) It dispenses with the use of mercury; (2) it is readily portable; (3) the air pressure is at all times under absolute control; (4) the extent of the oscillations is sufficiently great to make accurate readings on the dial very easy.

A series of comparative tests was made, using a mercury manometer as a standard. Pressure registrations were identical with both instruments. A similar model has been in constant use in my wards for the past two years. It has required no repairs, and, recently standardized with the Stanton instrument, showed a difference of only five millimeters, a negligible quantity in practical work. Von Recklinghausen has had a similar satisfactory result with his model.

This instrument is manufactured by the Wappler Electric Controller Company of New York, 39 East Sixty-third Street.

39 East Sixty-third Street.

A SIMPLE METHOD FOR PREPARING A USEFUL STAIN.

By ROSCOE W. KING,

LAS ANIMAS, COL.

The following working formula is the outcome of a long series of experiments covering three or four years:

Methylene blue (Grubler's)	1.0
Sodium acid carbonate (C. P.)	0.5
Sodium acid sulphate (C. P. crystal)	0.72
Distilled water q. s.	

Dissolve the methylene blue and the sodium acid carbonate in 100 c.c. of distilled water. Transfer to a porcelain dish (500 c.c.) and evaporate to dryness directly over the flame, a wire gauze being used to distribute the heat. The solution should be allowed to boil gently until one-half to two-thirds of the water has escaped. The heat is then somewhat reduced, evaporation hastened, and spurting prevented by occasionally tilting and rotating the dish so as to cause the fluid to flow upon the sides of the dish. When perfectly dry, and almost cool, add the acid sodium sulphate previously dissolved in ten to fifteen c.c. of distilled water. Rotate and tilt the dish to bring this acid solution in contact with all of the stain in order to insure complete neutralization of the sodium carbonate present. When effervescence ceases again evaporate to complete dryness over the flame. Remove the stain by means of a small spatula and keep as free from moisture as possible.

The blue stain as made above is permanent. It can be used in aqueous solution in all cases in which a well polychromed methylene blue is desired. For tissue work a slightly alkaline solution is quite as satisfactory as Unna's. The sodium sulphate has no injurious effect whatever, while it probably serves to keep the powdered stain more nearly free from moisture than it would be without the sodium sulphate. This is, of course, desirable. The writer has always used Grubler's stain in preparing the blue, but experiment might show that another brand was as good. Some grades of methylene blue will not work at all, but so far only one lot of Grubler's

has been found that did not give satisfaction. This was thought to be mislabeled, as it had not the physical appearance of methylene blue. The working formula as given above is adapted only to the preparation of the quantity of stain mentioned. If larger amounts are desired separate dishes should be used. One of the necessary requirements for success seems to be that the time required for evaporating the blue solution to dryness should be between one-half and one hour. This always occurs when the volume of the fluid is 100 c.c., and the directions are followed. It is obvious that were the volume increased five or ten times the action of the alkali on the blue stain would be greatly prolonged, the result being an over oxidation, amounting to a destruction of the staining properties. Large volumes could, of course, be evaporated within the time limit by correspondingly increasing the surface of the dish exposed to the heat.

The principal use of the stain, and the object for which it was especially prepared, is in the making of a modified Romanowsky staining fluid. This being easily and quickly done by dissolving 175 milligrams* of the blue in 25 c.c. of methyl alcohol containing 40 milligrams of eosin (Grübler's W. J.). The eosin may be kept as a stock solution by dissolving 0.8 grams in 500 c.c. of methyl alcohol. The blue stain is readily soluble, and the Romanowsky stain is ready for use immediately after its addition to the eosin solution. Filtration is apparently not necessary, but it is probably preferable to filter after a few hours. The Romanowsky staining fluid made in this way has identical staining properties with Wright's, Leishman's, and others. Washing or other differentiation is, however, not required. In staining blood smears on the slide it is best to draw a heavy line with a grease pencil about half an inch from each end. Drop on about twenty drops of the stain, or enough to cover the film well, allow to act one minute and then add an equal number of drops of distilled water and allow to remain from three to five minutes. In some cases longer staining may give better results. Almost any kind of methyl alcohol will give a staining solution that gives satisfactory results. But if an impure alcohol—especially one containing water—is used the staining solution will not keep so well as when absolute alcohol is employed. Any alcoholic solution of a Romanowsky stain will at times be found to overstain with eosin or with the blue. In the former case a drop of alkaline alcohol (0.5 per cent. NaOH in ethyl alcohol), and in the latter a drop of acid alcohol (3 per cent. HCl.) will usually remove the trouble.† Thick blood films always overstain with blue, and for this reason the smears should always be made as uniformly thin as possible.

*For routine blood work it is better to employ only 150 milligrams of the blue, as a larger quantity gives a fluid which tends to overstain.

†This can also be overcome by remembering that the greater the amount of water used for diluting the stain the more intensely will the eosin stain. Thus, if equal amounts of stain and water do not stain the nuclei distinctly, it indicates that to 20 drops of stain only 15 drops of water should be added. The presence of a scum on the surface is not a reliable guide.

U. S. Naval Hospital, Las Animas, Cal.

Mammary Gland Extract.—The mammary gland is said to secrete or contain a substance which stimulates the uterine muscle.

Blood Pressure in Children.—According to Stowell (Archives of Pediatrics), the blood pressure in healthy children is usually between 91 and 103 mm. of mercury.

Fixation of Bile Pigments in the Placenta.—Odorico Viana has made a study of the placenta in eight cases of jaundice in pregnancy, four of which were merely catarrhal cases, while four showed acute yellow atrophy of the liver. The examination was made to ascertain whether the death of the fetus, which generally occurs in the severe cases, and is absent in the catarrhal ones, was due to the carriage of bile pigments to the fetus by the maternal blood. The author finds it much more likely that the death of the fetus is caused by toxins passing from the circulation of the mother than by bile pigments. It must be admitted that a certain amount of bile pigment is deposited in the tissues of the placenta, especially the sincitium. There is no reason to believe that the pigment is combined with the lime of the placenta. The presence of bile pigments in an alcoholic extract of such a placenta is not a demonstration of the deposition of the bile salts, because those found may come from the blood that is contained in the placenta.—*Annali di Ostetricia e Ginecologia.*

Racemose Ovarian Cysts.—Le Jemtel describes racemose ovarian cysts, consisting of agglomerations of several cysts attached to a central pedicle formed by the ovary. Such a cyst he observed in a patient from whom he removed it. They are of variable size, without an enveloping membrane. The cyst may be implanted on the most prominent part of the ovary which is of normal character. The liquid contained is transparent and sticky. The walls are very friable. The ovaries contain graafian follicles in process of development. The solid portion of these tumors consists of a tissue rich in mucus, with connective tissue cells, and large vessels with thin walls. The epithelium varies in characteristics, from cylindrical with cilia, to cuboidal. These tumors may be extraovarian or ovarian, and may constitute true supernumerary ovaries. The clinical history gives no characteristic symptoms that will aid us in making the diagnosis from other ovarian cysts. They appear at any age, and develop slowly or rapidly. They are very soft, and quite mobile. The only possible method of treatment is by ablation of the cysts and ovary.—*Annales de Gynécologie et d'Obstétrique.*

Pulmonary Emphysema and Fatty Degeneration of the Diaphragm in Diphtheritic Intoxication.—G. Mya has observed in children who were subject to severe diphtheritic intoxication a condition of emphysema of the lungs, which may go so far as rupture of the vescicles of the lungs and sub-pleural, and even subcutaneous emphysema. The type of case in which this is seen is that in which there is a necrotic angina with great enlargement of the glands of the neck, myocarditis, albuminuria, cutaneous hemorrhages, and muscular asthenia. Such cases generally result fatally. In life the area of resonance of the lungs extends down to the seventh rib in front and the twelfth behind, and the vesicular murmur is enfeebled, while inspiration is short and superficial. In these cases there is no laryngeal stenosis, and hence the condition cannot be referred to the extra effort required for respiration. At autopsy the clinical evidences are confirmed by finding the macroscopic and microscopic characteristics of emphysema. In these cases there is also found a fatty degeneration of the muscular fibers of the diaphragm, which aids the lack of elasticity of the lungs, due to deficient power of the elastic fibers in producing the emphysema.—*Rivista Di Clinica Pediatrica.*

Hypertrophy of the Lymphoid Tissues of the Pharynx and Its Relations to Tuberculosis.—P. Nobécourt and Leon Tixier have examined twenty-two children from thirty-one months to four years of age, all of whom had large adenoids and enlarged tonsils, but none of whom had pulmonary tuberculosis. They sought for appreciable tuberculous lesions and used tests for the presence of tuberculosis; the subcutaneous method, ophthalmic reaction and skin reaction were used as tests. A table of the results is appended. Bacteriological and histological examinations of the tissues removed were made. Of the children thirteen had no sign of tuberculosis: six had doubtful signs; three were considered clinically tuberculous, and two were clinically doubtful. The skin reaction was positive twelve times; the ophthalmic reaction was positive four times; only five infants out of the twenty-two could be considered free from tuberculosis, and yet almost all enjoyed excellent health. The portions of tissues removed and examined never showed tuberculous foci. The authors conclude that tuberculosis of the tonsils and adenoid tissues of the pharynx is rare. In these children who were openly tuberculous the inoculation of guinea pigs with the tonsilla tissue never produced tuberculosis. The lymphoid tissues did not serve in these cases as the door of entry for the bacillus tuberculosis.—*Gazette des Hôpitaux.*

MEDICAL RECORD.

New York, July 17, 1909.

DIAGNOSTIC REACTION OF TUBERCULIN ON THE NASAL MUCOSA.

FOLLOWING in the direction suggested by von Pirquet, Wolff-Eissner, and Calmette, two physicians of Bordeaux, Lafite-Dupont and Moulinier, have made certain observations on the effect of applying tuberculin to the nasal mucosa and record their results in the May issue of the *Annales des Maladies de l'Oreille*, etc. They declare that they have in this way obtained a characteristic reaction in the form of a peculiar exudation which dries and forms a yellow crust upon a congested mucosa from which clumps of extravasated red cells project here and there as minute reddish points. Observations were made on one hundred patients taken by chance. Only those with tuberculosis in some form reacted. Use was made of the dry tuberculin prepared at the Pasteur Institute in Lille in one per cent. solution in distilled water. Cotton tampons were soaked in this solution, eight tampons being placed in half a cubic centimeter of it, and assuming that the tampons absorbed equally, each one represented 0.000625 of dry tuberculin. The tampon was then inserted in the nose and for ten minutes the patient was cautioned against violent breathing, coughing, or using the handkerchief. This time was found to be quite sufficient to produce the reaction, a lengthening of the time making it neither more pronounced nor more speedy in appearance. The authors consider the septum preferable to the turbinate as the site of application because the former possesses fewer glands and the secretions are naturally less abundant.

The characteristic of the nasal reaction is the appearance at the point of application of a localized exudation preceded by a more or less intense congestion of the mucosa which sometimes persists after the distinct exudation has passed off. The latter soon dries under the influence of the air and becomes a light thin yellowish crust. The reaction comes on in from eighteen to forty-eight hours after the application of the tuberculin and disappears in from seven to eight days. Occasionally it persists for ten and even eleven days. The crust generally falls off from the fourth to the sixth day. If it is forcibly removed, another crust forms containing more or less blood and remaining for a longer time than the primary deposit. Examination of the latter has shown a considerable number of white cells with altered nuclei, especially the polynuclear variety, and the predominance of this polynucleosis harmonizes with the results of cytological examinations made in the ophthalmo-reaction.

Out of the 100 patients examined 90 received the tampons on the septum and 10 on the inferior turbinate. Of the former, 17 had pulmonary tuberculosis, pleuritic lesions predominating, 21 had tuberculosis complicating some previous affection, while 11 had surgical tuberculosis, and 20 were non-tuberculous. Observations were incomplete in 10. All the tuberculous patients gave a positive reaction, even those with pulmonary cavities, although in this class the reaction was not so pronounced. Three of the pleurisy cases not reacting were in patients presenting conditions of bodily decay in which the reaction does not present itself by any method, confirming results already obtained in the ophthalmo-reaction. Thus one was cachectic, one syphilitic, and one had a true serofibrinous pleurisy without any bacillary element. In short, 68 out of 73 tuberculous patients reacted in the manner described. Of the 5 others, 3 presented a congested mucosa without the exudate and 2 are still under observation.

According to Lafite-Dupont and Moulinier, the nasal procedure is just as reliable as the ophthalmo-reaction and the cutireaction. Over the former it has the advantage of being absolutely harmless and over the latter that of applicability without the knowledge of the patient.

MILK SUGAR AND THE CALORIE METHOD OF INFANT FEEDING.

SINCE Heubner, a few years ago, carried out his experiments on the energy requirements of the infant, the calorie method of feeding has been adopted almost universally throughout Germany and is attracting some attention among the younger pediatrists in this country. The method employed in the German clinics is to make a milk and water mixture which the physician believes the child can digest, calculate the energy equivalent of this in terms of heat units, and add enough milk sugar to raise the calorie content of the food to between eighty and one hundred and twenty calories for each kilogram of body weight, the figures arrived at by Heubner as the energy requirement of the healthy infant. In this country, when the calories are calculated, it is done more often as a guide to the quantity of a definite mixture to be given than as a method of determining the quality of the food or the percentage of sugar to be added.

This dependence upon the use of milk sugar to make a food of the proper nutritive value for the infant would seem *à priori* to be a rational procedure, as lactose is the form in which nature administers carbohydrates to all suckling animals. That there may be some doubt, however, as to its efficiency is brought out in an article by Richard Weigert in the *Berliner klinische Wochenschrift* for May 24, 1909. In his position in charge of the city milk dispensary in Breslau, he was able to study a large number of healthy and ill infants. Before he took charge the routine diet given to the very young infants requiring artificial feeding was a mixture

consisting of one part of whole milk and two parts of a ten per cent. lactose solution. On a certain day he stopped all the lactose distribution from the dispensary and in its stead diluted the milk with plain water. The results were watched with great care and it was shown that the infant's weight increased as rapidly and as regularly without the milk sugar as it did with it. Certain symptoms, such as redness of the mouth and frequent, thin, slimy stools, which had been common, disappeared immediately. No increase of constipation nor the passage of soapy stools was observed. For the past year all infants fed from the Breslau dispensary have received mixtures without the addition of lactose and have gained as well and have been generally in better health than before.

A point of even greater interest than the inefficiency of lactose, is, if Weigert's charts are to be believed, the gain in body weight of his patients on a diet so extremely weak that, according to the tables of Heubner, it should be quite incapable of sustaining life. According to these charts, Weigert's infants, before the elimination of milk sugar, received but some seventy calories of food per kilogram of body weight and afterward between twenty-five and thirty-five calories. Though the amount of milk was rapidly and disproportionately increased soon after the lactose was stopped, it rarely got above fifty and never above seventy-five calories per kilogram. The fact that infants can gain weight and thrive on such an extremely low diet is quite contrary to the teachings of Heubner and his school. If these results of Weigert, which have stood the test of time for a year, continue, a new minimum limit may have to be given to our rules for the energy requirement of healthy and ill infants. The entire piece of work gives the pediatrist plenty of food for thought.

BLOOD TESTS FOR MENTAL DISEASES.

During the past year some marked advances have been made in our means of diagnosing certain forms of mental conditions and steps have been taken pointing to the possibility of more exact methods of diagnosis of the psychoses. Not the least of these is the butyric acid test of Noguchi for the globulin or globulin-like substance found in excess in the spinal fluid and blood of syphilitic and parasyphilitic patients, by which he is able to differentiate these from the other forms of psychoses.

There now appears still another definite laboratory test in an article by Much and Holzmann, who describe in the *Münchener medizinische Wochenschrift*, May 18, 1909, a new hemolytic test for certain mental diseases. They give no explanation of the theory of the test, nor do they tell by what steps they reached their results. The principle of the reaction is as follows: Washed human blood corpuscles are dissolved by cobra venom. The addition of healthy human serum does not interfere with the hemolysis, but the serum from patients with certain forms of psychoses does prevent the solution of corpuscles by venom. The exact technique is as follows: Cobra venom from Ehrlich's laboratory is used, 0.2 gm. being dissolved in 10 c.c. each of water and of glycerin, and kept on ice. In the test of 0.35 c.c. of serum is mixed with 0.25 c.c. of a 1:5000 venom solution, the dilution from the stock solution being made with physiological saline solution. To this is added 0.5 c.c. of a 10 per cent. suspension of human corpuscles, the blood having been obtained with a sodium citrate solution and the corpuscles twice washed with physiological salt solution. The mixture stands in the thermostat for two hours and for twenty-two more on ice. At examination the tube is shaken. If the solution is completely opaque the reaction is positive. A partial restriction of hemolysis, where, though the fluid is not transparent, some solution has taken place is considered as a negative result. The shaking is essential to the reading of the results. Hemolysis may occur in the control within two hours, but it will always have taken place by the end of twenty-four hours when the fluid is kept on ice. This reaction the authors call the "psychoreaction." They examined some 400 patients. Of these they report upon 151, of which number 42 gave a positive reaction and 109 a negative one. Of the positive cases twenty-four were classified as of the manic depressive type, ten as dementia præcox, and seven as having a family history of manic depressive insanity. From their results the authors conclude that their test is specific for both dementia præcox and cyclic insanity either in the patient or in his family.

If this new reaction should stand the test of time it would undoubtedly prove of value to the alienist in diagnosing certain obscure cases of mental disease. A careful critical study of the article, however, impresses one with the necessity of a repetition of the work by less enthusiastic observers. Too many of the cases classed as manic depressive insanity, in which the reaction was positive, were otherwise diagnosed before the test was made; and, on the other hand, a number sent to the observers as cases of this condition, in which the reaction proved negative, were promptly considered as of some other form of dementia. In one or two positive cases the authors state that the patients were mentally normal, and no family history of insanity could be obtained. If, too, the reaction holds from an insane grandmother through normal parents, it loses much of its value. The pure empiricism of the test, which is given with no effort at explanation, would also argue against its acceptance. In the Noguchi test it was known that the spinal fluid contained an excess of globulin in syphilis and the step from that to tabes and general paralysis was a logical one, the test being a test for globulin. The reaction of Much and Holzmann has no such basis and it can hardly receive general acceptance until it has undergone more rigid investigation.

Gastric Secretion During Pregnancy.

One of the most trying experiences that the physician meets in the course of his duties is the care of a persistent case of the vomiting of pregnancy, and he who throws light on the etiology of this disease which may lead to a more intelligent and successful

therapy will be a benefactor of his kind. Many theories have been promulgated as to the cause of this distressing affection, varying from the direct pressure of the gravid uterus to a faulty metabolism making the condition a milder grade of eclamptic toxemia, none of which theories seems, however, to have accomplished much toward preventing or relieving the attacks. For this reason every addition to our knowledge of the physiology of the condition should be greeted hopefully as a possible step toward the goal of prevention. Such an addition has, perhaps, been made in a small piece of experimental work carried out by Borodenko and reported in the *Berliner klinische Wochenschrift* for June 7, 1909. This investigator studied the gastric secretion of a pregnant dog by the common method of the "Pawlow stomach." The examination began two months before the termination of pregnancy and continued until after the end of lactation. The dog was in good health during the entire period. At first the gastric juice showed no abnormality, but, as pregnancy advanced, the secretion decreased steadily and the acidity lessened markedly, until at the end of pregnancy, and on the day of birth, the content of the Pawlow stomach consisted of mucus only, and was neutral or slightly alkaline in reaction. Shortly afterward the gastric juice reappeared and gradually increased, remaining low, however, in both quantity and quality until the end of lactation, when it rapidly returned to the normal. With the steady decrease in the acidity the animal's appetite underwent a change. Whereas at first she took meat, bread, and milk with equal avidity, as the pregnancy approached its climax she developed a marked fondness for milk, cared much less for meat, and refused bread entirely. During the nursing period the appetite slowly reverted, and at the end of lactation the dog again took all three foods with equal relish. Whether this decrease in gastric secretion is due to a lack of salts in the maternal organism, owing to the extra deposit in the fetus, or to some more obscure metabolic change, it is within the realm of possibility that the vomiting of pregnancy is in some way related to or dependent upon such a physiological change. Though it is not to be expected that a means of preventing or curing the vomiting of pregnancy will be obtained as the result of one experiment on a dog, still the findings of Borodenko are sufficiently striking to receive serious consideration, in the hope that they may prove the basis of more extended and fruitful investigation.

Iron as a Substitute for Bismuth in *X*-Ray Diagnosis.

During the past few years the practice of giving bismuth subnitrate to patients in doses of a size previously unheard of has become quite common. This is due to two new uses of the drug, the one in *x*-ray diagnosis, and the other, an outcome of the first, the treatment of tuberculous sinuses by mixtures of bismuth and vaselin, as recommended by Beck of Chicago. Both of these uses of bismuth have been distinct advances in medical science and have led not only to more accurate diagnoses, but also to some remarkable cures. At the same time, however, this use of the massive doses of bismuth subnitrate has recalled to us a fact previously well known, but apparently forgotten by the new generation of medical practitioners, namely, that this drug is far from innocuous and if used too freely is liable to cause serious or even fatal results. Its action appears to be twofold, both the bismuth and the nitrate radical causing definite symptoms of poisoning. These intoxications are serious, for even when not fatal they are chronic in nature and may cause decided discomfort over periods of many months. In this connection it is of interest to find in the *Münchener medizinische Wochenschrift* for June 8, 1909, a brief note by Karl Taege of Freiburg describing a method by which iron can be substituted for bismuth in *x*-ray diagnosis. The objection to a watery suspension of iron is that the metal sinks rapidly, and is not evenly distributed, while an oil emulsion is disagreeable to physician and patient alike. Taege, therefore, suggests as a substitute an emulsion in tragacanth. He grinds iron oxide in a mortar with tragacanth powder and then shakes the mixture thoroughly with water in a flask. Enough tragacanth must be used to make the final watery solution contain about one per cent of the substance. This gives a syrupy fluid in which the iron oxide remains in suspension for hours. If this iron preparation acts as well in obstructing the *x*-rays and is less toxic than bismuth subnitrate, it should prove a valuable substitute for the latter more dangerous drug.

News of the Week.

Medical Camp at Antietam.—An army medical camp will be held at Antietam from July 15 to August 15, in connection with the army maneuvers. It will be under the command of Major Frederick P. Reynolds, who will have as his chief aids Capt. R. H. Patterson, Capt. Frank W. Weed, and First Lieut. Charles W. Cullen of the Medical Corps. About 250 of the best-trained veterans of the Army Hospital Corps will assist these officers. There is to be a fully equipped field hospital, where daily instruction in the care of the sick and wounded will be given. The hospital will be conducted on the lines of a field hospital during warfare. Sanitation will be another important part of the exercises. Every appliance to rid camps of garbage and of mosquitos and other insects will be used.

New York City Play Grounds.—To meet the overcrowding in the vacation playgrounds of New York City, the Board of Education this week opened 64 additional playgrounds. Lessons at the playgrounds continue from 1 until 5.30 P. M. From 1 to 1.30 the children assemble, chant a salute to the flag and sing folk songs. Then follows an hour of games and athletics. From 2.30 to 3 the time is spent in organized free play and recess. An hour of free hand drills, work on light apparatus, military drills, and folk dances is followed by forty-five minutes of games and gymnastics; a half hour of athletics, racing, jumping, etc., and fifteen minutes of assembly and dismissal. In addition, 72 playgrounds for mothers and babies and morning playgrounds will be opened.

Official Recognition of the Dog Star.—The Health Department of New York has again ordered the destruction of all dogs not muzzled or held in leash, the order to be effective until September 1. This is an excellent regulation, but why it is put in force only during July and August of each year is not apparent.

An Anti-Noise Ordinance.—The Mayor has

signed the ordinance, recently passed by the Board of Aldermen, prohibiting all blowing of horns, shouting, or other methods of attracting attention to their wares on the part of hucksters and peddlers, except in that curious survival, known as "Paddy's Market," in Ninth Avenue.

Appointments.—The Memorial Hospital of Richmond (Va.) has had a complete reorganization of its medical staff. Dr. Lewis C. Bosher is chief of the surgical staff, and the following additional appointments have been made: Seniors, Dr. Edward P. McGavcock, dermatology; Dr. St. George Grimm, pediatrics, and Dr. R. H. Wright, ophthalmology. Juniors, Drs. C. W. Massie, Hunter R. Scott, H. B. Sanford, and T. D. Jones, obstetrics; Drs. McCaw Tompkins, and H. Norton Massey, abdominal surgery; Drs. Sidney Baker and B. Giles Cook, gynecology; Dr. E. H. Terrell, general surgery, and Drs. B. M. Rosebro, E. W. Gee, and B. L. Taliaferro, diseases of children.

Dr. M. P. Ravenel, director of the State Hygienic Laboratory, Madison, will be placed at the head of the Wisconsin Pasteur Institute, which was recently established in connection with the State Laboratory.

Dr. H. Gideon Wells has been appointed professor of pathology in the University of Chicago, and Dr. A. G. Carlson has been appointed professor of physiology in the same institution.

Resignations.—Dr. S. M. Yutzy has resigned from the medical faculty of the University of Michigan, after eighteen years' service.

Dr. H. B. Ward has resigned from the medical faculty of the University of Nebraska.

A Conference on Prevention of Infant Mortality will be held at New Haven, Conn., on November 11 and 12, 1909, under the auspices of the American Academy of Medicine. The work of the conference will be divided into four sections—medical prevention, philanthropic prevention, institutional prevention, and educational prevention. The subjects will be discussed by many pediatrists and social workers in the country. The committee on local arrangements will be under the chairmanship of Dr. W. Merriman Steele of New Haven, and the secretaryship of Prof. C. J. Bartlett of New Haven.

The Phipps Psychiatric Ward.—Plans have been completed for the new psychiatric ward of the Johns Hopkins Hospital which is to be built by Mr. Henry Phipps, of New York. The building will be of dark brick and stone to resemble the other buildings of the hospital, but the interior will be quite different from the usual hospital ward. The white coloring common to hospitals will be omitted, and the rooms will be made as homelike as possible. The idea of non-restraint will be carried out as much as possible. The court will be made into a garden, and the windows will be guarded by flower boxes and trellises instead of bars. Extensive arrangements for recreation and exercises will be supplied.

A Dispensary for Epileptics.—A few months ago there was formed in Philadelphia a Society for the Securing of Suitable Employment for Epileptics. The unusual response and numerous demands made upon this new organization by helpless and neglected epileptics, have made the establishment of a dispensary, where they may receive treatment and medicine without cost, an absolute necessity. This will be called the Letchworth Clinic for the Home Treatment of Epileptics. This clinic and the parent society will have for their object, besides the enlightened sanitary supervision of these unfortunates, the study of all means for the prevention and care, as well as cure, of epilepsy; and since the disease is increasing, the urging upon the State the enactment of law prohibiting the marriage of epileptics until at least three years after recovery. An effort is being made to obtain the necessary funds to provide a suitable dispensary equipment for such service.

A Clinic for Mental Defectives has been established at the Long Island College Hospital out-patient department. Here advice is given to mothers, teachers, and guardians as to the diagnosis and care of mental defectives. At present the clinic is held each Tuesday afternoon, at 2 o'clock, under the charge of Dr. Siegfried Block.

Department of Public Health at Harvard.—Harvard University has announced the establishment of a department in its medical school exclusively devoted to the subjects of public health and preventive medicine, and the election of Dr. Milton J. Rosenau, now director of the Hygienic Laboratory of the U. S. Public Health and Marine Hospital Service, as Professor of Hygiene and Preventive Medicine. He will be at the head of the new department. Dr. Rosenau will begin his service at Harvard with the opening of the next college year.

A Memorial to the Late Captain Henry Lomb, presented by the employees of the Bausch and Lomb Optical Company, was recently unveiled in Rochester. It is in the form of a bronze tablet resting like an open book upon a pedestal of Siena marble. The tablet bears, at the head of the inscription, the following words, being Captain Lomb's last public utterance and spoken to the directors of the Rochester Public Health Association, June 5, 1908, in answer to their request for advice: "Think of others first, yourselves afterwards."

The Cholera Epidemic in St. Petersburg is gaining headway. During the twenty-four hours ending at noon July 10 there were 124 new cases and 42 suspects reported at the municipal hospitals.

Anti-Vivisectionist Congress.—At the International Anti-Vivisection and Animal Protection Congress, held in London last week, Mrs. Belais of New York made one of her characteristic speeches in which she said that the salvation of both animals and man depended on disproving the germ theory of disease.

A Trachoma Hospital.—A special hospital has been established at the Phoenix Indian School, under the charge of Dr. Ancil Martin, assisted by Dr. W. W. White and Dr. W. H. Harrison. The hospital is designed to be a training station for Indian Service physicians and nurses, qualifying them especially for treating trachoma.

A New Hospital for Tuberculosis.—Ex-Governor Benjamin B. Odell, Jr., has presented to the tuberculosis committee of Newburg, N. Y., a hospital and camp for the treatment of tuberculosis patients. He has transferred to the city a plot of four acres of high ground near the city. The dwelling on the property will be used as an administrative building, and there will be a modern infirmary which will accommodate twenty-five patients. The cost of the hospital will be about $25,000.

The Addition to Saint Joseph's Hospital, Bloomington, Ill., recently built at a cost of about $75,000, was opened for public inspection June 19 and 20, 1909. This addition includes about seventy rooms and wards.

The Jewish Consumptive Relief Society of Chicago dedicated its building for female patients June 27. The building has been presented to the Chicago-Winfield Tuberculosis Sanatorium, and is said to accommodate ten patients.

The University of Louisville Medical Department at its commencement exercises on June 30, graduated 182 men. This is the first class to be graduated since the consolidation of the various medical schools of the city, and is the largest class ever graduated in the State of Kentucky.

Consolidation of Colleges.—On June 15 the trustees of Carroll College, at their annual meeting, voted unanimously to accept the proposition of the Wisconsin College of Physicians and Surgeons, Milwaukee, to affiliate with that institution. Dr. T. C. Phillips has been appointed Dean of the Wisconsin College of Physicians and Surgeons, the new Medical and Dental Departments of Carroll College.

The Vermont Medical School Alumni Association at the annual reunion in Burlington on June 29 elected the following officers: *President*, Dr. U. A. Woodbury of Burlington; *Vice-Presidents*, Dr. W. Bryant of Ludlow; Dr. P. E. McSweeney of Burlington; Dr. M. F. McGuire of Montpelier; Dr. C. Fletcher of Dover, N. Y.; Dr. D. D. Grout of Waterbury; *Secretary and Treasurer*, Dr. Lyman Allen of Burlington.

Obituary Notes.—Dr. SAMUEL B. TOMLINSON of Cincinnati died on June 25, 1909, aged 81 years. Dr. Tomlinson was graduated from the Ohio Medical College in 1856 and was the oldest practising physician in Cincinnati.

Dr. RUSSELL G. ANDREW, for forty years a practising physician at Navesink and the Highlands, N. J., died at his home at Navesink on July 6 in his sixty-ninth year. He was a graduate of the Albany Medical College in 1866, being at the time of his death the sole surviving member of his class.

Dr. RAPHAEL ASSELTA, prominent in the Italian colony of New York, died July 9 in the New York Hospital while undergoing operation for an affection of the throat. Dr. Asselta was 52 years old and received his degree from the University of Naples in 1884. He came to this country soon after, and had since practised in New York.

Dr. CHARLES D. JACKSON of Denver, Col., was killed by a street car in Denver on June 28, aged 27 years. He was a graduate of the Western Pennsylvania Medical College in 1904.

Dr. ANDREW J. DOWER of Brooklyn died at his home, July 10, from pneumonia, aged 57 years. He was a graduate of the Bellevue Hospital Medical College in 1878. At one time Dr. Dower was a member of the Board of Education of Brooklyn. He was a member of the Kings County Medical Society, the Long Island Medical Association, the New York State and American Medical Associations.

Dr. JAMES M. KELLEY of Griffin, Ga., died at his home on July 2, aged 56 years. He was a graduate of the Bellevue Hospital Medical College in 1878. Dr. Kelley was until a short time ago chief surgeon of the Second Regiment National Guard of Georgia, with the rank of major.

Dr. HUGH L. MANNING of Louisville died on July 1 in Manchester, Ky., aged 41 years. He was a graduate of the Louisville Medical College in 1898 and of the Hospital College of Medicine, Louisville, in 1899. He held a chair in the faculty of the latter institution.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING'S BIRTHDAY HONORS—QUEEN'S FÊTE FOR CHILDREN'S HOSPITAL — WEATHER — BIER'S METHOD—SPINAL ANALGESIA—ROYAL SOCIETY'S CONVERSAZIONE—PHYSIOLOGY INSTITUTE AT UNIVERSITY COLLEGE—AMBULANCE PROPOSALS—EXPERIMENTS ON ANIMALS—OBITUARY.

LONDON, June 25, 1909.

THIS is the King's birthday—not the actual, but the official one. A long list of honors conferred in celebration of it is issued this morning. No new peers have been made, but there are 12 baronets and over 30 knights, with promotions in various orders. The profession is not forgotten. A baronetcy is conferred on Mr. Henry Morris, P.R.C.S., and Sir Dyce Duckworth is advanced from knighthood to the same rank. Lieutenant Colonel Leishman is among the knights. Surgeon-General L. D. Spencer, M.D., I.M.S., retired, H.K.S., advances from C.B. to K.C.B. Surgeon-General Whitehead, P.M.O., southern command, receives C.B. Lieutenant-Colonel Robert N. Campbell, I.M.S., inspector civil hospitals, receives C.I.E. So does Edgar Thurston, L.R.C.P., superintendent Madras Museum. The C.M.G. is conferred on Professor W. J. R. Simpson, M.D., for services on various missions in connection with plague; also on P. J. Garland, Dept. P.M.O., Gold Coast, in recognition of similar services at Africa.

The "Queen's fête," as some are calling the fair opened by Her Majesty on Wednesday, is on behalf of the oldest and most important Children's Hospital, established in Great Ormond street 60 years ago. You know its great repute, as do other countries. But it is in debt, as usual, £9,000 and its expenditure regularly exceeds the income. The Queen takes a great interest in it, and the great fête under her auspices, which remains open until to-night, is expected to raise a considerable sum. It certainly ought, for it is the most picturesque and fashionable of the season. It takes the form of an antique French garden of the time of Louis XV., and arranged to resemble Versailles. The garden beds, enclosed in stays of box and orange trees, are visited, and among them hundreds of ladies wander about in the dresses of the period. There is a theater, too, where an entertainment is provided of the Madame de Pompadour order, and in which she appears. Scattered about are kiosks, which serve as stalls, where curios and other gifts are exhibited under the presidency of duchesses and other noble ladies who have worked enthusiastically for the success of the fête. To-day all the exhibits will be put up to auction, and, as all have been given, there is great hope for the hospital funds, especially as from the generosity of the promoters and helpers there are no expenses to deduct from the returns. The day is also marked by two performances in the theater and a variety entertainment by eminent artists. The closure is fixed for 10:30 o'clock.

The weather has been the only drawback. Each day we have had cold and rain enough to dissipate the old superstition of Queen's weather, and to-day many thousands will be disappointed of their holiday in honor of the King's birthday. June has indeed done its utmost to make us forget the sunshine we had in part of May. Statistics are quoted to show that this summer, so far, promises to be a precise replica of that just 100 years ago. Yet, while we are shivering, we learn from Reuter that you are suffering from a "heat wave" which may portend a too great change in store for us.

Bier's method of treatment does not seem to gain ground in London, as the results seem to be rather uncertain, if one may judge by the conversation of surgeons who have tried it. This impression is supported by a discussion at the Dublin Academy, where Mr. Atkinson Stoney read a paper describing the means of producing passive hyperemia. In septic inflammation he had found the method more promising than in tuberculosis. He was emphatic in his warning not to produce too great a degree of hyperemia. Pain, he held, must not be produced, nor excessive pressure applied, or sloughing might occur.

Mr. Lentaigne (president) thought Mr. Stoney had explained why some unsatisfactory results had been reported. He had seen many tuberculous cases deteriorate under the treatment, but he had recently been converted to its use for boils. Mr. Gunn had tried it in knee and wrist cases, but it always produced pain. Perhaps Germans were less sensitive to this.

Mr. Wheeler had had the same results—pain. But in some cases of gonorrheal origin there seemed improvement.

Mr. Pearson understood that pain followed the bandage plan as a matter of tension, but suction might relieve at first by reducing atmospheric pressure.

Mr. Stoney, in reply, said Bier's worst results were with the knee joint; why, he knew not. He did not suggest the method where better and quicker results could be obtained by operation.

At the West London Society Mr. Canny Ryall brought forward on the 4th inst. the subject of spinal analgesia, which he uses for all sorts of operations, and believes it has many advantages over general anesthesia. He has injected for craniectomy, extirpation of larynx, excision of one-half the tongue with glands of neck, etc. He injected a child of two and one-half years. In Vienna he injected an old woman from whom Eiselberg removed most of the thyroid (over 12 ounces). The results he attributes to Jounesco's discovery, which led to combining strychnine with novocain, and so neutralizing the depressant effect and preventing respiratory paralysis. He gave a dog 20 centigrams of novocain without death following. He rarely uses lumbar puncture; for operations on the upper part of the body he inserts the needle into the first dorsal space, and for those on the lower half into either the eleventh or the twelfth. There is no advantage, he says, in making the puncture higher, for perfect analgesia, lasting for an hour or more, can be obtained in the head and neck by injecting between the first and second dorsal spines. The great danger of spinal analgesia is respiratory paralysis, but now that it is known that strychnine completely antagonizes novocain, Mr. Canny Ryall urged that every one employing the method ought to feel it his duty to combine the two drugs in all cases.

The Royal Society held a conversazione last evening. The invitations included the delegates to the Darwin centenary celebration at Cambridge, of which you will have had full accounts, for your own country has been well represented among the scientists assembled from the whole civilized world.

The exhibits at the conversazione were as interesting as usual on these occasions. One man declares they cover the whole field of science, from changes in comets to microbes and radiation. A sample or two must suffice. There was on view a luminous watch and night compass. The dial is of transparent glass, at the back of which a compound, containing radium bromide, is pointed, rendering it easily read in the dark. Dr. Waller demonstrated the electrical variations of the human heart by Einthoven's galvanometer. The researches at Cambridge on the malignant jaundice of dogs, which is prevalent in India and on red water in cattle, were illustrated. A section of the aorta of the Pharoah of the Exodus, showing calcification, was also on view, as were many sections of fossils from different countries, and a great number of other most interesting exhibits.

The Physiology Institute of University College was opened this day week in the presence of a distinguished assembly. Lord Reay, vice-chancellor, presided and thanked the donors who had made the building possible which was the growth, not of an isolated college, but of the university itself. Mr. Haldane performed the opening ceremony, and said the equipment in physiological research would put the institute into the first position among the universities of the world. In the last 20 years great progress had been made, and a number of new universities (which he enumerated) had been founded and technical colleges rivaling the great German polytechnics. There was a distinct awakening to the absolute necessity of the progress of the nation in the highest kind of knowledge. Even the treasury had been interested. He wished he could be as happy as to other branches of education.

The institute is the first step in a larger scheme for providing all that is required for medical science and education. The cost, including equipment, is put at £20,000. But £30,000 in addition is wanted for the requirements of anatomy and pharmacology. The ground floor is devoted to physiological chemistry, and the laboratory will accommodate 96 students. There are, further, a research laboratory, or private laboratory, and rooms for distillation, combustion, gas, and optical studies. Above is the great theater, library, and departments for neurology, histology, and for aseptic experiment. In one wing is a large class room; in the other a demonstration theater, sterilization and operating rooms, an animal hospital, and a room for keeping monkeys. Refrigerating chambers and machinery occupy the basement, and animal sheds the yard. The institute is under the direction of Professor Starling.

The asylums board adopted, on Saturday, a report of its ambulance committee to the effect that it is prepared to extend its system so as to provide 10 additional stations in London, with call boxes in the busiest thoroughfares and at difficult crossings. The board is further prepared to inaugurate an efficient service for the county and outlying police district. The cost is estimated at £10,000 per annum.

The report of last year's work in experiments on live animals has been issued as a White Paper by the Home Office. There were 453 licences, and all have furnished reports; all are declared to be persons of the highest scientific standing and well qualified for the work. The experiments have been made in suitable places, duly registered, and the usual inspections have been made. Numerous experiments have been made, mostly simple inoculations. Seventy county councils have their own laboratories, in which bacteriological experiments were carried on, and a sewage farm was used for testing the effluent on fish. Two thousand experiments were performed for the tuberculosis commission, and many others for government departments and health authorities; many, also, for testing sera and vaccines and standardizing drugs. The inspector says the animals were well cared for and the requirements of the act observed. Some trifling irregularities happened by mistaking the precise application of the different certificates.

The death occurred on Wednesday of Professor Daniel John Cunningham at Edinburgh, where he had been Professor of Anatomy since 1903 and Dean of the Faculty of Medicine. Born in 1850, he was the son of Dr. J. Cunningham, Principal of St. Mary's College, St. Andrews. He took M.B., Edinburgh, 1874, and M.D., 1876, when he was appointed Demonstrator of Anatomy in the university. He was professor at University of Dublin from 1883 to 1903, when he received the Edinburgh chair. He has served as Examiner at the Universities of London, Edinburgh, Cambridge, Oxford, and Victoria, as well as for the military and naval examinations. He had been president of the Royal Zoological Society and vice-president of the Royal Society of Dublin, served on the South African Hospitals Commissions, etc. His scientific contributions are well known. He was acting editor of the *Journal of Anatomy and Physiology*.

Letters from the Sleeping Sickness Camp, Kisü, British East Africa, announce the death on June 10, from malaria, of Dr. Henry Hugh Baker, at the age of 31. He was an Oxford graduate, M.A., M.B., and B.Ch., all taken the same year (1905). He took the medical classes at St. Mary's Hospital, London. He was government medical officer at Nairobi and had previously served as medical officer at Kharga Sasisis, West Egypt.

The death occurred yesterday of Dr. Nathaniel Hobart, the oldest doctor in Cork, and perhaps in the kingdom, for he was over 90 years of age. In his time he had served as senior surgeon to the City of Cork Hospital and Infirmary, and had also served on the staff of the Eye and Ear Hospital and other institutions. He took M.R.C.S. as long ago as 1846 and M.D., Glasgow, 1847.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

BENCE-JONES ALBUMINURIA—TETANY CURED BY TRANSPLANTATION OF PARATHYROID GLANDS—THE EFFECTS OF ADRENALIN IN TETANY—NEW OPERATION FOR TRIGEMINAL NEURALGIA—HIGH FREQUENCY CURRENT AS A SOURCE OF HEAT—ANGIOMA VENOSUM RACEMOSUM LEADING TO ASTERIOGNOSIS—THE NATURE OF ANAPHYLAXIS—EXPERIMENTS WITH HEPATOTOXIN.

VIENNA, May 15, 1909.

DR. PAUL GERBER has reported a case of Bence-Jones albuminuria, which he had recently observed. The peculiar behavior of the urine on addition of acetic acid led to the discovery of this rare condition. The patient was a diabetic, 56 years old, who constantly showed sugar in the urine, usually amounting to less than one per cent. The addition of acetic acid and of potassium ferrocyanide to the urine led to the appearance of a moderate cloud, which could be estimated to amount to not more than ½ per cent. of albumin. On the other hand, quantitative estimation of the protein contained in the urine, the usual albuminometer being used, gave much higher values, reaching as high as 12 per cent. The biuret reaction was very marked. The addition of concentrated acetic or nitric acid to the urine led to the formation of a marked precipitate, the fluid being very quickly transformed into a thick, gelatinous mass. The substances which could be precipitated from the urine by the addition of alcohol or of ammonium sulphate gave the typical reactions of Bence-Jones body.

Dr. Julius Boese has lately observed a case of tetany

coming on after the removal of a goitre. The patient was a girl of 20 years, who was suffering from a large colloid goiter which had compressed the trachea, producing a saber-like deformity. During the operation care was taken to leave intact the posterior capsule of the gland as well as the upper lobes. Very severe tetany appeared 24 hours after the operation; the administration of parathyroid extract as well as other remedial measures proved quite without effect, and transplantation of parathyroids was decided upon. These organs were obtained from another patient in whom a unilateral goiter was removed. The glands were transplanted pre-peritoneally, and the effect of the operation was most marked. The phenomena of tetany, which seemed to endanger the life of the patient, disappeared very quickly, and three days after the transplantation she was quite free from symptoms of the disease.

Falta and Rudinger have made several experiments with the use of adrenalin in the idiopathic tetany of laborers. It has been found that the subcutaneous injection of one mgm. of adrenalin in a normal human being leads to a well-marked rise of blood-pressure. The rise in pressure appears quite gradually two to four minutes after the injection of adrenalin, and reaches its maximum six to eight minutes after the first rise. The rise as measured by the Riva-Rocci instrument reaches thirty to sixty mm. of mercury and continues from one-quarter to three-quarters of an hour. In four cases of tetany, on the other hand, quite a different result has been observed by the authors. In all of them the maximum rise of pressure could be noted three to four minutes after the injection of adrenalin. In one patient the blood-pressure rose from 90 to 180 mm. of mercury; in another it changed from 115 to 165. The other two patients likewise showed more marked effects from the use of adrenalin than is usually seen in normal persons. Of great interest was the fact that in all patients the use of adrenalin led to acute exacerbations of the tetanic phenomena. Generalized paresthesia appeared, the phenomenon of Chvostek was much more marked, the fingers of both hands were bent in various forced attitudes, and the lower extremities were forcibly extended. In one case there even appeared a severe contraction of the abdominal muscles and a temporary spasm of the glottis.

Professor Julius Dollinger of Budapest has tried a new method of operating in trigeminal neuralgia. The removal of the Gasserian ganglion in this disease has proved to be a dangerous procedure because of the hemorrhage from the cavernous sinus which was usually wounded during the operation. In order to avoid this complication Dollinger has decided not to extirpate the ganglion at all. Instead he pulls out the roots of the ganglion from under the tentorium cerebelli and divides them. Dollinger has operated in this fashion in three cases of severe trigeminal neuralgia. The operation was very successful in the case of the first patient, the bleeding being insignificant and the time of the procedure quite short. The result was very satisfactory, the patient having been relieved of his trouble and having remained quite free from pain for the several months that have elapsed. Indeed, he has been able to take up his former trying vocation, that of an officer in active service. Although good results were obtained by Dollinger in the other two cases, he admits that hemorrhage and technical difficulties may occur with his method of operating as well. A physiological advantage of his technique consists in the fact that by leaving the Gasserian ganglion intact a branch of the sympathetic leading from it to the bulb is preserved. Accordingly, the pupil remains quite unchanged after this operation. Dollinger expects to modify his operation still further by dividing as far as possible the nerve fibers that carry sensation and leaving intact such others as supply the muscles of mastication, these latter fibers being usually placed below and to the median line of the former. It is quite possible that with this modification the operation for trigeminal neuralgia will show much less untoward result than has been the case heretofore.

Erich von Bernd has constructed a very handy piece of apparatus with which he has been able to apply thermotherapy to deep lying tissues of the body. It consists essentially of a transformer by means of which high frequency current is obtained from the usual electric supply. When such high frequency current is passed through the tissues the latter are subjected to a uniform degree of heat. The intensity of the current and therefore of the heat can be modified at will. Indeed, it is possible to apply enough heat to coagulate the proteins of some portion of the tissue, and such portions then may be removed by the knife without any loss of blood. The application of such current during an operation for carcinoma prevents the implantation of living cancer cells into the surrounding healthy tissue. However, it must be remembered that the bloodlessness of such a procedure is only temporary, because the thrombi produced by the current are not very extensive or firm. All divided vessels must, therefore, be carefully ligated so that postoperative hemorrhage may not occur. If a lesser amount of electricity is used the heat may be applied as a therapeutic measure; a joint, for instance, simply need be placed between the electrodes to have heat applied to its deep tissues. In this manner it has been possible to kill gonococci in an infected joint within one-half hour, after which various mechanical measures such as massage or traction may be applied without the danger of aiding the infection. In old processes of whatever origin the heat acts by producing hyperemia and by diminishing pain. In one case brachial neuritis was very favorably influenced, while in cases of fracture, etc., the formation of callus was distinctly modified by the use of the current. Uric acid derivatives present in the joints appear to be dissolved by the heat, but are later again precipitated. Cancer tissue covered by healthy skin is made soft and almost fluid by the current, yet the overlying skin is not at all affected; after the application of heat in this manner, *x*-rays seem to be much more destructive to the cancer tissue. Care must be taken, of course, to regulate the current properly, for harm may be done by the application of too much heat. In the treatment of air-containing cavities, especially, the current must be modified properly, for such cavities offer increased resistance to the high-frequency sparks and too much may quite easily be used. The procedure may prove quite useful in the treatment of the diseases of the prostate and in the presence of extravasated blood in the body.

Julius Flesch has recently reported a case of a man, fifty-six years old, who showed the curious phenomenon of loss of tactile memories, though sensation of touch was not abolished. This symptom is always a sign of cortical disease and in this patient there were enough external evidence to make it probable that a lesion of the cortex likewise existed. He showed numberless dilated vessels, forming tumors and folds in the upper eyelid of the right eye, in the right temporal region, and elsewhere. Like dilatations of blood-vessels must have been present in the right orbit, for the eyeball was pushed into one corner and there embedded in a net of enlarged veins. The bones on the right side of the skull were eroded so much that the external plate was almost absent and the spongy structure of the diploe could be felt by the finger. In some places it seemed as if the bone was absent altogether, nothing but dilated vessels being placed between the brain membranes and the external coverings of the skull. Enlarged veins were likewise present in the nasopharynx and could be seen hanging downward behind the arch of the palate. Compression of the internal jugular vein led to a marked swelling of the external dilated vessels, and the patient experienced at the same time a sensation of dizziness and fullness in the head. Coughing and letting the head hang down likewise led to an enormous increase in the size of the vascular mass. The connection between the disturbances of sensation, marked by asteriognosis and the tumor seemed quite evident. The tumor could be classified as an angioma venosum racemosum originating in a vascular nevus. The growth of the vessels has in the course of time resulted in the destruction of the bones of the skull. It was quite probable that the veins of the arachnoid were involved in the process, being dilated and pressing upon the underlying brain tissue. The latter has probably led to some changes in the cortex, resulting in the singular disturbances of touch.

Drs. Biedl and Kraus have been studying the question of anaphylaxis in an experimental way. They have noted that injections of Witte's peptone can result in an antianaphylaxis for serum, and that animals that have passed through an anaphylactic stage for serum become much less sensitive for Witte's peptone. These data justify the assumption that the anaphylactic symptom-complex has much in common with the phenomena produced by poisoning with Witte's peptone, the action of peptone having much to do in producing ana-

phylaxis. It may be supposed that Witte's peptone and the toxin which is active in the production of anaphylactic phenomena are somewhat similar to each other physiologically; perhaps they attack the same structures in the organism, producing paralysis of the peripheral vasomotor apparatus and diminishing the coagulability of the blood. The subsequent phenomena mentioned above, that is, antianaphylaxis on the one hand and immunity to peptone on the other, may be explained by the lack of reaction in the paralyzed tissues to the additional toxic action. However, in both cases there occurs a gradual recovery of the reactive power; the blood-pressure assumes its normal height and may then be again reduced by other factors having this effect, such as the division of the spinal cord or of the splanchnic nerves. It may again be supposed that the same substance which is active in the production of anaphylaxis is responsible for the toxic action of Witte's peptone, rather than that these two substances are different, though attacking the same structures. Physiologically Witte's peptone and the anaphylacting body may be considered, therefore, as identical substances, so far as their action is concerned.

Dr. Joannovics has attempted to immunize rabbits with a cellular extract obtained by washing and mincing the livers of cats. The animals were immunized by intraperitoneal injections of this substance, the injections being continued for the period of two and a half years. The serum of such rabbits proved to have a marked effect upon cats. Three cats died very shortly after receiving injections of such serum, three others died in two to four months. In the case of the latter animals there was found a fatty necrosis of the liver, much of the parenchyma being likewise replaced by connective tissue. Other portions of the organ showed regenerative phenomena in the liver cells and in the bile passages. The other organs were in the main normal. It seemed as if the serum was specifically toxic for one organ, namely, the liver. Moreover, it was specific for the kind of animal used. The absence of hemoglobinemia, of icterus, and of hemoglobinuria spoke against simple hemolytic action of of the toxin. Large doses of this "hepatotoxin" seemed to paralyze the respiratory function, though the heart continued to beat in a normal manner. The animals could be saved by the use of artificial respiration, but they gradually became marantic, refusing food and losing flesh and strength. This method of studying the condition of the organism after gradual destruction of one organ may enable us to gain some insight into the specific functions of the different organs of the body.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

TYPHLITIS IN BERLIN—THE NEW INSURANCE LAWS—TEST FOR DEMENTIA PRÆCOX AND CYCLIC INSANITY

BERLIN, June 15, 1909.

THE Berlin Medical Society has had a collective investigation on the subject of typhlitis in Berlin for the year 1907. At the session on May 12 the etiology and symptomatology were presented by von Albu and the therapeusis by von Rotter. Questions had been answered by 134 physicians. It could not be shown that the disease was becoming more serious, nor could it be determined whether the infection came from the intestines or from the blood. In 100 cases there had been a mistaken diagnosis, in that the condition was confused with some gynecological trouble. In hospitals the mortality was 9.2 per cent.; in private practice, 1.7 per cent. of the cases treated. For every acute case, two of the chronic recurrent type were found. It is most common between the tenth and twentieth years of age. Though the disease is rarer in more advanced age, the steady rise of the mortality curve shows that it is more dangerous. Abdominal pain, fever, and vomiting are the three main symptoms. The observations show that the occurrence of the spasm of the abdominal muscles increases with the severity of the attack.

Rotter stated that there had been in all over 2,900 definite cases, of which 2,300 were treated in hospitals with a mortality of 9 per cent. There were 1,344 cases operated upon, with 14.6 per cent. mortality; in the early operation the mortality was 5.6 per cent. in 423 cases: after 31 days, 18.8 per cent. in 921 cases. Of 1,021 cases without operation the mortality was 1.6 per cent. It is worthy of note that only a small proportion of the cases came to operation in the first or second day. On the third and fourth day the operation mortality increases five to tenfold. As most of the fatalities occur in the first attack, and the later attacks are apt to be less severe, the interval operation is not to be recommended.

The further development of the insurance laws, of which the summary has been published, brings new large groups of people within the limits of labor insurance. But it appears that the regulations concerning the struggle which the German physicians have for years carried on against the injustices of the present laws toward them have been entirely neglected. The profession is therefore raising its voice far and wide. Since the profession has been interested in this question for a long time, it seems worth while to describe it carefully:

The new law, as an essential step, broadens the sickness insurance to include various classes of workmen, laborers, servants, and others. We expected from it a decided simplification in the mode of treating the individual cases. We had hoped that the three great institutions—the sickness clubs, the industrial societies, which take over the care of the sick after they have left the sickness clubs, and the invalid stations, which attend to the patients who have become chronic—would be improved by the new law. It is evident that this treatment of the same patient in three institutions causes much needless work and waste of money. The hoped-for union was defeated on political grounds. The physicians regret this on both social and hygienic grounds. Such a great comprehensive organization could accomplish much in the sphere of hygiene. But such a centralization of the single units has been accomplished to but a very small degree. In Germany alone there are 23,000 sickness clubs, each with its own administering apparatus.

Entirely new relations appear in regard to the government of the clubs by the physicians. Whereas before the choice of the system of medicine to be used depended solely upon an agreement between the physician and the club, and in no instance was the physician forced to any definite system, by the present laws general councils are formed. These councils are without representation from the physicians and have charge of the clubs and their regulations, their judgment being final. It could, therefore, easily happen that a system of medicine might be adopted of which the profession disapproved. This was sufficient to increase tremendously the bitterness which the German profession has long felt concerning the position of the club physician. What the profession at large thinks about this matter will be shown at the "Physicians' Day" at Lübeck. We must therefore wait for a complete discussion of the position of the profession until after that meeting.

A word should be said in this place concerning a significant discovery of the two Hamburg physicians, Much and Holzmann. They found that in manic depressive insanity and dementia præcox a small amount of some material circulates in the blood, the presence of which may be proved by a biological reaction. The reaction also appears in patients who show no sign of cyclic insanity, but in whose family it has occurred. The reaction consists in the blood of such patients preventing the hemolytic action of cobra venom on normal blood.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 1, 1909.

Some Analogies Between Malaria and Syphilis.—W. H. Deaderick says that these two diseases present more striking analogies than any other two in the whole field of medicine. Both have manifestations varying in intensity from the mildest to the most severe. Both to be acquired must be inoculated. Both have stages of latency. The deposit of melanin in malaria may be regarded as analogous to the formation of the gumma in syphilis. They are the only diseases for which we possess almost true specifics. In both, proper drugs cause the rapid disappearance of the immediate lesion, but mercury and the iodides are powerless against the resulting cicatrix, which may eventually kill; while in pernicious malaria, with localization of parasites, quinine may kill the organism, it avails nothing against the amelioration of peri-vascular exudation, hemorrhages or necrosis depending on parasitic occlusions. Both have para-sequelæ against which the remedies used are powerless. Too early application of the specific drugs has the same disastrous effect in the diagnosis in both cases. Physicians have learned the necessity of continuing specific treatment for two or three years after the subsidence of active symptoms, but they have not learned to do the same thing with quinine after malarial

outbreaks. The danger to the community arises in the latent stage in each malady. The syphilitic is often so visibly affected that he is shunned and seeks treatment promptly, but the malarial patient in the latent stage believes himself cured, takes no medicine, and may be a source of infection for an indefinite time.

Resuscitation After Relative Death.—C. R. Metcalf refers to recent literature on resuscitation after relative death, saying that generally men rely on hypodermic medication and artificial respiration. If the patient's heart is still beating such methods may be successful, but artificial breathing has no effect on a pulseless heart. Arrest of the heart signifies relative death. With the onset of flaccidity recovery cannot occur spontaneously, but will follow only radical efforts. Presence of heart beat cannot be determined by auscultation. Reference is made to the heart massage of Schiff in experiments on dogs, and to the work of Prus, who used artificial respiration, heart massage, and arterial infusion of normal saline, plus 3-100 per cent. of saccharate of soda. Experimental coronary perfusion and attempts at resuscitation in experimental animals, too long continued, have been followed by fibrillary tremor of the heart instead of normal pulsation. Stewart and Crile have shown that a combination of artificial respiration, heart massage, occlusion of the aorta, and arterial injection gives the best results. The success of this combination is limited by ante-mortem clotting, overdistension of the heart, later cardiac failure, and imperfect recovery of the brain. Authentic records of 44 cases are at hand, including the author's four. Of the 44, no less than 33 have been anesthesia syncope, 24 chloroform, 6 ether, 1 a mixture, and 2 unknown anesthetic. Of the other 11, 1 each in pulmonary embolism, suicide by hanging, diphtheria, acute cardiac dilatation, 2 each tracheal asphyxia, traumatic injury of the brain, and electric shock. Of the 14 cases, 9 have met with complete recovery, secured after relative death; 8 have been partly successful, while the remaining 27 have been failures. Of the 9 successful cases (summarized by the author), 4 have been after ether, 3 after chloroform, and 2 from an anesthetic not named. Of the 8 temporary cases recovering, but later proving fatal, 5 have followed chloroform, 1 tracheal asphyxia, and 2 brain injuries. Permanent recovery has not followed unless intervention was begun within 12 minutes after apparent death. Massage should not be discontinued before 30 minutes have elapsed, although 30 seconds have proved efficacious. Not infrequently a considerable time elapses between the return of the heart beat and the reestablishment of breathing. Until the latter returns, artificial respiration must be kept up. Subdiaphragmatic massage appears to be the safest and most practicable way of reaching the heart. Any abdominal incision will suffice. This route affords rapidily, is free from the danger of pneumothorax, and does not interfere with artificial respiration. The paper of Metcalf is of extreme interest and will well repay careful reading.

Principles of Therapeutics by Sense Culture.—P. W. Goldsbury says that rest and stimulation are the principal lines of therapeutic procedure and have been employed for general and local disorders by various measures. Muscular activities have been used in promotion of both these lines. Nervous activities, including those of the special senses, have not been as systematically studied, though instances of their empirical introduction as healing measures are common. Recreation by means of the special senses should be employed as contributing to general and local health, and the employment of such measures may be made more systematic and scientific. It is the purpose of the writer to prove that the special senses as nerve organs, no less than the orther organs and muscles, need for their healthful development this same adjustment of rest and stimulation, and, as the brain must be rested somewhat by readjustment of energies within itself, the different sense organs may be refreshed by varying and qualifying forms of stimulation peculiar to themselves. Physical culture seeks to recreate by variations of the expressive or muscular activities. Why should not variations of stimulation for the avenues of impression, the special senses, be used for their tonic effect?

New York Medical Journal, July 3, 1909.

Complications of Malarial Fever.—J. M. Swan gives the detailed histories of two cases. Case 1 was one of quartan malaria complicating chronic parenchymatous nephritis, and Case 2 one of estivo-autumnal malaria complicated by bronchopneumonia. In Case 1 the nephritis was considered to be independent of the malarial infection, because the cure of the latter had no influence on the former. The return of the dropsy, with chest pains, chills, cough, and blood-tinged expectoration from which the patient, a man recently from Jamaica, died, was unaccompanied by the recurrence of the sporulating parasites in the peripheral blood, and examination of the bone marrow after death failed to show malarial pigmentation. The author quotes Thayer as saying that in the Baltimore region, albuminuria is of frequent occurrence in malarial fevers, that it is more frequent with the malignant tertian parasite, and that at least in tropical countries malaria may play an important part in the causation of chronic renal disease. In Case 2, that of a sailor, smears made from expressed spleen pulp showed a large number of pigmented macrophages and a fair number of deformed and partly degenerated parasites. During life there were no symptoms suggesting pneumonia. Naked-eye appearance at autopsy suggested only the usual hypostatic congestion, but under the microscope a peculiar exudation was seen, consisting of erythrocytes, polymorphonuclear leucocytes, granular matter, and large uninuclear cells containing malarial pigment. The author is inclined to believe that the pneumonia in this case was due to the irritation of the malarial pigment on the lung tissue.

Histological Changes of the Spinal Cord in Pernicious Anemia.—The patient of A. Gordon was a man of 48 years, clerk, whose symptoms dated back four years and followed an accident in which he lost considerable blood. The course of the anemia was not unusual. A complete autopsy was made, and the following changes were found in the spinal cord: The most marked degenerative state was found in the lower cervical and upper thoracic segment. In the lower cervical region the anterior columns on both sides, Gowers's tract on one side, the direct cerebellar and crossed pyramidal bundles on both sides were profoundly degenerated. Only a small portion of fibers were preserved around the comma. The posterior columns were almost entirely degenerated except the middle portion near the median line corresponding to the comma of Schultze and the very posterior portion. There were a great many vacuoles in the degenerated segments. The upper thoracic segment showed still more degeneration than the preceding one. Here the anterior columns, direct cerebellar, and crossed pyramidal tracts were markedly affected on both sides. Disseminated foci of degeneration were found in both Gowers's columns. Goll's and Burdach's columns were almost totally destroyed. Vacuoles were present along the borders of the posterior columns. The process of degeneration in the lower segments of the cord was less and less marked, so that in the lumbar portions the crossed pyramidal bundles alone were in a state of mild degeneration. A few degenerated fibers were seen only very anteriorly, and vacuoles in a linear distribution were noticeable in the posterior columns near the median line.

Treatment of Diabetes as an Infectious Disease.—A. King says that he has been able to obtain a pure culture from the blood of *Saccharomyces cerevisiæ* in every case of diabetes he has examined since his attention was drawn to the possible infectious nature of this disease. His general conclusion is thus stated: Because diabetes is a disease of fermentation, because the yeast fungus is found in the blood, because its actions explain all the symptoms as well as the pathological conditions, because the patients show a disturbed power of resistance to this fungus, and because this lowered resistance is increased by treatment with vaccine, he believes this yeast fungus is the cause of diabetes and that it should be treated as an infectious disease. As to treatment, he notes the indications to be restoration of resisting power, removal of causes, and of complications. The lowered resistance may be removed by the action of vaccines and the careful regulation of the diet. In the diet, some starch food should be used to prevent other fermentations of fats and albuminoids, which give rise to more serious toxic substances. The destruction or removal of the cause may be accomplished by the use of antiseptics, by increasing the phagocytic action of the leucocytes, and by maintaining a healthy activity of the kidneys. To prevent, relieve, or remove the complications there must be a relief from mental worry, a careful regulation of the diet, a promotion of oxidation by the use of those remedies which will improve the oxygen-carrying function of the blood, and by deep breathing exercises in fresh air, which at the same time assist in the removal of the excessive amount of carbonic acid gas from the body.

Journal of the American Medical Association, July 3, 1909.

Prophylaxis in Infants.—Thomas S. Southworth says the reduction in infant mortality has not been so great as we had supposed before the publication of the researches of Newman in England and Stowell in this country. This need not surprise us much if we consider the growth of the slums in great cities and the decreasing

prevalence of maternal nursing. The improvement of antenatal conditions is a sociologic rather than a medical question, but much can be done by the profession toward decreasing the early mortality of children. A careful study of the problem has convinced Southworth that women do not of choice neglect their children, but have often prematurely weaned their infants from bad advice. He shows how large a part ignorant midwives may play in this matter, but medical men are also partly to blame. Instead of weaning, the breast milk should be still utilized and supplemented by other methods under medical supervision. Turning our attention now to the exclusively bottle-fed babies, we find ourselves much better equipped to cope with a difficult case. He does not speak highly of the percentage system as practiced, but criticises the tendency to employ a very limited number of inelastic formulas. The supervision of the growth and development of the bottle-fed infant, as practised, leaves much to be desired. It should not be left to the mother or nurse between the seventh and twentieth months, and periodical and regular inspection are certainly advisable. Diet is not the only factor needing medical oversight. Next to a normal proportion of muscular tissue, the hemoglobin may be called the most important index of the child's resistance. Parents seldom notice any slight pallor, and fresh air in abundance and at all times is one of the most effective agents in producing good blood. A complete rearrangement of the infant's hygiene may be even more effective than the administration of iron in bringing about improvement. Fresh air, however, alone, without attention to its unobstructed entrance to the lungs, is not sufficient, and possibly no single factor recently employed has been more effective than the attention given to hypertrophied tonsils and adenoids. There is still much to be done, as full inspection will show. Valid contraindications are rarely seen in early surgical attention to these matters, even before the expiration of the first year of life if symptoms of mouth breathing are present. The neglect of children's teeth is also mentioned by Southworth as not fully appreciated, and the eye also should receive attention, as it has of late years. In fact, it has been much less neglected than the ear, which has only begun to receive prophylactic attention. The ear is especially implicated in many infectious diseases, and the conscientious physician who wishes to do his full duty must carry with him in his pocket the means of examination of the ear. More cases of otherwise unexplainable temperature can be traced to the ear than to any other complication, and these cases can be relieved by paracentesis. This is the conservative operation, according to our modern ideals, as by relieving congestion in cases of effusion it limits the process and aids recovery. There is less apparent glory in patient prophylaxis and conservative methods than by later successful intervention, but prophylaxis is and should be the ideal of our profession.

Dropsy of the Optic Nerve Sheath.—J. A. Tenney discusses the theories of optic neuritis and reports several cases in which sudden loss or impairment of sight, with or without headache, occurred without ophthalmoscopic appearances to correspond or other things in the history or symptoms that would aid in the diagnosis and treatment. In all these cases he adopted a treatment based on the theory of intracranial pressure as the cause, and recovery followed. It consisted of moderate doses of potassium iodide, sometimes increased if not at once effective. He has never used pilocarpin in such cases, of which he has seen a number, thinking the iodid might, with its alterative action, more efficiently prevent the return of the symptoms.

Acute Pellagra.—N. P. Walker reports a summary of the observations on fifty-one cases of pellagra occurring among the colored female insane patients at the Georgia State Sanatorium previous to January 1, 1909. He does not report any conclusive facts proving the disease due to corn diet, and in some cases this seems improbable unless the toxins are retained for long periods of time before their effects appear. In the majority of instances, dermatitis, stomatitis, and diarrhea were noticed simultaneously among the first symptoms. Vomiting is ocasionally an early symptom, and slight rise of temperature and indefinite abdominal pains may be complained of. The dermatitis is almost always symmetrical, and, in some cases, contrary to some recent writers, it may occur on the palms of the hands or the plantar surfaces of the feet. The stomatitis also varies in extent and severity, and vaginitis occurred in about 12 per cent. of the cases. Diarrhea was present in all cases at some time or other and was absent in the beginning in only two or three. In the later stages constipation may replace it. The nervous symptoms are not so constant as would appear from the description of the chronic forms. Many of the cases running an acute course do not show spinal cord symptoms at all. Just preceding death, marked delirium may supervene, and a general mental reduction is often present. The blood of one patient presented a typical picture of pernicious anemia, and some other cases presented points of interest. Hemoglobin varied from 65 to 95 per cent. and red cells from 2,500,000 to 5,292,000. Nucleated reds were found in three cases, and may appear comparatively early in the disease, while the hemoglobin is still normal. Of the patients who developed the disease in the sanatorium a few have recovered from the pellagrous symptoms. These numbered 12, or 26 per cent.; 6 patients were removed before the termination of the disease; 28 of the remaining 45, or 62 per cent., died.

Interstitial Keratitis.—H. Gifford says that the more he sees of interstitial keratitis the more convinced he is that Hutchinson is right in attributing practically all of it to inherited syphilis. He refers only to the typical form which occurs almost always between the ages of three and sixteen years, and almost never after twenty-five. The prophylaxis of the condition, therefore, resolves itself for practical purposes into the prevention of syphilis and the cure of syphilis, more particularly of the hereditary form. He does not attempt to cover the whole field, but simply lays stress on certain peculiarities of the teeth as aids to diagnosis, on the treatment of the disease when it has broken out in one eye, and on the prophylactic management of children marked with the disease but without active manifestations. He thinks it highly probable that if all children between the ages of three and sixteen showing the signs of inherited lues could receive a long, continuous course of treatment, the number of cases of interstitial keratitis and of syphilitic deafness could be greatly reduced. The ordinary signs are well enough known, but he calls attention to certain peculiarities of the so-called Hutchinson teeth, the bulging of the lateral lines of which he considers as the most permanent feature. As regards the milk teeth, Hutchinson in his second paper made some important observations which have practically passed into oblivion. One of these refers to a condition which he illustrates in which the incisors are small and discolored, while the canines are healthy looking. This is a common symptom. Other figures show another peculiarity of the milk canines on which Hutchinson lays great stress and which Gifford has seen a number of times. A central discolored blunt peg projects from and is separated by a shallow groove from a base or collar of normal-looking tooth tissue. If we imagine the same sort of defect in a molar tooth, we shall have a symptom on which great stress has been laid by Darier. Gifford considers such molar teeth and the peg-shaped milk canine fully as characteristic as the Hutchinson incisor. Another form of syphilitic tooth on which Darier lays stress is the tuberculated permanent canine which is also figured by Gifford. He also mentions another form of first permanent molar which he calls the slope molar, in which the base is much wider than the crown, which is probably due to the same influences of malnutrition. Formerly he placed little reliance on the use of specific remedies, but of late years he has followed a more vigorous treatment and with better success. He thinks that he has the best results since adding arsenic to the treatment. Summing up, he says that he thinks the following points may be made with reference to the prophylaxis of interstitial keratitis: "First, in the text-books which treat of the diagnosis of hereditary syphilis, instead of the single faulty cut of the teeth so commonly used, at least half a dozen figures should be presented to show not only the varieties of the Hutchinson tooth, but the other more important forms of syphilitic teeth mentioned in this paper. Second, all children in public institutions and in private families who show any of the well-marked signs of inherited syphilis should receive a course of antisyphilitic treatment, even if in other respects they seem to be entirely well; the results and indications of this treatment being controlled, if possible, by the serum diagnosis test. Third, when a case of syphilis, inherited or otherwise, appears in a family, all other members of the family should be examined for signs of the disease, and if such are found, should be subjected to specific treatment. Fourth, by an extra vigorous use of specific treatment the disease may be kept out of the second eye in a larger proportion of cases than has hitherto been thought possible."

The Lancet, June 26, 1909.

Oral Sepsis in Its Connection with Throat Disease.—G. I. Stewart discusses this topic under the headings of signs of oral sepsis and the effect of oral sepsis on the

throat generally and particularly on the tonsils, adding some observations on the physiological function of the tonsil and other adenoid tissue in the pharynx. The signs are enumerated, as redness, swelling, heat, local pain, increased secretion and loss of function of all the muscles of the oropharynx, viz., the buccal, oral, and lingual muscles which forward the food particles to the gullet, keep the mouth clear of food, cleanse the teeth, and, in connection with the pharynx, promote proper articulation in speech. The author regards the lymphoid tissue in the pharynx as essentially protective in function by means of leucocytosis. Every inflammatory attack destroys a portion of this protective and resisting tissue. As regards the removal of tonsils which have become so diseased as to be no longer a barrier to infection, but an actual invitation to further microbic invasion, we should first remove the local cause and then the lymphoid tissue itself, if necessary, but the latter should not be done until the former has been attended to. The teeth must be looked after and the brush used regularly. Any furtehr obvious cause of oral sepsis should, of course, be removed. Neglect of these rules accounts for unsatisfactory results after tonsillar and adenoid removal.

A Case of Inherited Tachycardia.—J. Kirkland reports the case of a man now 56 years old, of independent means, average build, but varying considerable in weight. In 1897 he had a bad heart attack, with hemorrhage, but no bacilli were found in the sputum. When he came under the author's observation, the heart beats varied from 120 to 240. There was a mitral systolic murmur and strong pulsation in the cervical vessels. The right lobe of the thyroid was enlarged and evidently irritated the pneumogastric nerve. There was a marked irregularity of the heart action, increased by any slight exertion. Digitalis preparations gave considerable relief, while strychnine hypodermically with a mixture by mouth of apomorphine and caffeine seemed to cut short the attacks. In a sudden attack, the patient finally died. The especial interest in the case centered about the matter of heredity. The whole family seemed to be subject to tachycardia. Both grandmothers, the father, the mother, the aunt, four out of six daughters, the three sons, and at least one niece were, or are, victims to heart lesions. The trouble did not show itself to any appreciable degree in most of these cases until at least early adult life. We cannot therefore say definitely how many of the fourth generation will escape, but from present appearances it is almost certain that more than the one will suffer.

The Effect of Diphtheria Antitoxin on the Tuberculo-Opsonic Index.—From the tabulated results given by A. G. Banks, it appears that there is no great variation in the index before and immediately after the injection of the serum. But in two days after a definite rise is apparent in the average index, and this gains significance from the even distribution over the individual readings. Age and dosage seem to have little difference. During some weeks following the injection, a somewhat low index to the tubercle bacillus is the rule.

British Medical Journal, June 26, 1909.

Pneumococcus Invasion of the Throat Upon Which Laryngeal and Pulmonary Tuberculosis Supervened.—This case is reported in great detail by Felix Semon, who refers to two other instances already put on record by him, of pneumococcus throat. The characteristic symptoms in the previous cases were profound asthenia, ulceration of the affected parts, almost entirely a febrile course, complete absence of swelling of the cervical lymphatic glands, pneumococci in almost pure culture or predominating over all other organisms, and eventually a punched-out loss of substance and finally the healing of the greater part of the substance without any cicatrix. The third case occurred in the person of a physician, and the course of events is indicated in the title of the paper. Death occurred after a lapse of five months from the initial symptoms. The two previous cases recovered, one spontaneously and the other during a iodide treatment. There was no doubt as to the correctness of the diagnosis. The history of the case is most interesting and cannot be reproduced here. A most striking fact was that at one time in the later stages cultures from the pharynx yielded almost a pure culture of pneumococci, while those from the larynx an equally characteristic picture of tubercle bacilli. Insufflations of anesthesia are mentioned as affording great relief to the painful swallowing.

Acute Pneumococcus Infection in the Pharynx—J. Elliott refers to the prevalence of pneumonia in Chester during the first three months of the current year and the occurrence in the course of this period of several cases of pharyngitis due to the organism of the chest malady. Influenza could be ruled out clinically, because the usual visitation of the latter disease came later, and several of the pharynx cases developed influenza, which ran a typical course. The author was unable to trace exposure of his throat cases to pneumonia cases, although, as said, the latter disease was unusually prevalent at the time. Cultures were taken from two of the pharnyx cases and were undoubtedly pneumococcic in character. The exact form the pneumococcus invasion of the throat may take is still undetermined. The organism has been found in one instance of tonsillar abscess, in one of pseudo-membraneous pharyngitis, in acute pharyngitis with high fever of short duration (nature proven by animal inoculations), but in none of these cases was there any ulceration or false membrane. Glandular enlargement has been very marked, and again has been absent. Finally reference is made to the dictum of Rendu and Bulloche who have summed up the various types of pneumococcus throat as follows: (1) proven—(*a*) suppurative; (*b*) pseudo-membranous; (2) doubtful—(*a*) follicular; (*b*) inflammatory; (*c*), herpetic.

Pneumococcus Vaccines in the Treatment of Pneumonia and of Some of Its Complications.—After a study of eleven personal cases, A. B. Harris says that, clinically, death in this disease usually comes from cardiac failure, especially in those virulent cases terminating about the fourth day of the attack. Under these conditions the vaccine treatment in many instances will indeed reduce the fever but fails to avert a fatal result. The toxemia already induced is too profound for merely the arrest of the infecting process to be successful. Hence the vaccines should be used at the earliest possible moment and be accompanied by the use of a antitoxin. It is not improbable that in the case of the pneumococcus the success of a vaccine is due not simply to the fact that it should be autogenous, but the fact of a vaccine being autogenous narrows down the issue to (1) the right organism being selected, and (2) the vaccine being prepared, if not unduly subcultured, from an organism of requisite virulence. Fraenkel's pneumococcus is, however, as far as we know, invariable; it is not like the streptococcus (Gordon) an inclusive term for several varieties. On the other hand, we know from the staphylococcus and colon bacillus that these may be so subcultured as to lose their original virulence, and that vaccines so prepared are of little use, therapeutically. If, then, a potent and reliable stock pneumococcus vaccine is to be obtained, it should be made from as virulent a strain as possible. There is unhappily no difficulty in the early months of the year in obtaining as much as is wanted. The truth of this argument can only be verified by a great number of observations. With regard to the treatment of acute pneumonia by inoculation, the practical conclusions which alone can interest the busy clinician are: (1) that successful inoculation for pneumonia is possible; (2) that inoculation does no harm; (3) that a vaccine from one or a number of virulent strains should be used; (4) that it should be introduced as early as possible; (5) that the estimation of the opsonic index is not necessary; (6) that the observation of the temperature and physical signs is in pneumonia a sufficient guide in gauging the repetition of the dose. Infections of the lung by the pneumococcus which fail to resolve after an acute pneumonia, as well as pneumococcic infections of other areas, ought certainly to be treated with a pneumococcic vaccine; and these cases appear to afford a reasonable prospect of success.

Berliner klinische Wochenschrift, June 7, 1909.

Adhesions of the Diaphragm.—L. Bassenge says that while the usual methods of physical examination teach us but little about the condition of the diaphragm that an *x*-ray examination of the chest is of value. It shows differences in the position of the diaphragm, its bilateral raising from increased abdominal pressure, due to meteorism, ascites, tumor, or pregnancy, its bilateral depression in emphysema, its unilaterally high position from distention of the stomach, enlargement of the liver, or onesided paralysis, and its unilateral depression from vicarious emphysema or from air or fluid in the pleural cavity. Further than these the author has found that the *x*-ray may give valuable information as to the quantity and quality of diaphragmatic adhesions. These are told by the abnormal shape of the diaphragm in the *x*-ray picture during forced inspiration, when the dragging of the adhesions may cause bulgings and angles in the contour of the diaphragm. Such adhesions may occur between the diaphragm and the parietal pleura or between the diaphragm and the pericardium. The author reports seven cases, and publishes the *x*-ray pictures showing the varying contour of the dia-

phragm caused by different kinds of adhesions. The author concludes that: (1) an *x*-ray examination is desirable in all affections of the thoracic organs. It is necessary on diagnostic, therapeutic, and social grounds if the ordinary methods of examination fail to demonstrate a cause for the patient's complaint. (2) Diaphragmatic adhesions, if not connected with a pleural sinus, can be diagnosed only by means of the *x*-ray. (3) The *x*-ray examination is especially necessary when the present trouble has been preceded by a disease of the heart or lungs or trauma of the chest wall.

Kidney Transplantation.—Ernst Unger says there are two classes of operations for organ transplantation: partial transplantation, in which only a portion of an organ is removed, and complete transplantation, where the whole organ is changed and the circulation maintained by anastomosis of the blood-vessels. He refers to the work of Carrel and then describes his efforts to duplicate them. His operation is Carrel's transplantation *en masse* of the kidneys. He carries out the latter technique very closely, except that apparently he neglected to impregnate his sutures and cover his vessels with vaselin, which is possibly the secret of Carrel's success. He performed the experiment seventy times in all, fifty times on cats and twenty times on dogs. Most of the animals died either during or immediately following the operation, one dog lived eighteen days after operation and voided normal urine, another five days, and a third twelve days. One cat lived five days. Most of his animals developed extensive thromboses and nephrites. On two other cats he implanted new kidneys without removing the old, by resecting the aorta and vena cava below the site of the renals. One cat lived ten days with the four kidneys. At death the implanted kidneys showed marked nephritis. In the other, after sixteen days of health the animal's original kidneys were removed. The animal died in three days of uremia. Those implanted kidneys also showed marked nephritis.

Münchener medizinische Wochenschrift, June 1 and 8, 1909.

The Spreading of Typhoid Fever Through a City.—Kayser has analyzed the cases of typhoid fever which occurred in Strassburg over a period of three and a half years—1903 to 1907—and discusses them at length as to the mode of infection. Ninety-three per cent. were true typhoid and 6 per cent. paratyphoid. In all there were 505 cases. Sixty-six, or 13 per cent., were imported cases. Milk drinking accounted for 26.7 per cent. of the cases. Only 14.6 per cent. could be traced to contaminated water, and these were frequently from bathing and swimming. Food infection accounted for 2 per cent. and direct contact for 11.9 per cent. These latter were usually from atypical undiagnosed cases. Occupation explained 4.9 per cent. This class comprised nurses and washwomen especially. The bacillus "carriers" played an important rôle, as 9.5 per cent. were traced to this cause. Improper toilet arrangements accounted for 2 per cent. only. Typhoid was found to occur especially in certain streets which the author called "typhoid streets." These he explains by the residence of "carriers" on these streets. The morbidity varied with the temperature, being lowest in February and highest in August. This the author believes is due largely to the increased thirst in summer and consequent increased liability to infection. Twenty-eight definite bacillus "carriers" were discovered. The Gruber-Widal test was of help in finding "carriers," as three-fourths of these gave positive reactions.

The Use of the Morning's Milk for Infants.—Berger says that when possible the morning milk should be used for infant feeding, as it is much more fresh and contains fewer bacteria than the milk of the night before. It must, however, be remembered that this milk is poorer in fat than the evening milk, and must therefore be given in somewhat larger quantity.

The Effect of the Removal of Police Supervision on the Spread of Syphilis.—E. Jacobi discusses this subject. Until April, 1908, there had been official segregation and regular medical inspection and licensing of prostitution in the city of Freiburg. The number of women was small, considering the size of the city, the university, and the barracks. On that date the licensed houses were closed and the inmates scattered. Jacobi reports the number of venereal cases attending his dermatological clinic before and after this date. During the last six months he had seen more initial lesions than during any similar period of his twenty years' experience. There was no increase in the soft sores or in gonorrhea. During the last six months of 1906 there were in the wards thirteen men with fresh leutic infection; during the same period in 1907 there were eleven, whereas in 1908 the number rose to twenty four. On the women's ward the number in 1906 was nineteen, in 1907 seventeen, and in 1908 twenty-nine, while the number of venereal cases was reduced to one-half. Jacobi considers that segregation and control is an important means of protection against the danger of specific infection.

The X-Rays for Prostatic Concretions.—Gösta Forrsell discusses the use of the *x*-ray in the diagnosis of concretions of the prostate gland. He made *x*-ray photographs of eleven cadavers, and then dissected out the glands. Among these there were two with prostatic stones. He also examined one hundred living patients. The author gives details of the exact position in which the patient should be placed in order that the symphysis may not hide the concretions. He intensified his plates. In thirteen of the one hundred clinical cases prostatic stones were found. These were of two types. The first type were found in ten cases and the second in three. In the first type the shadows of the stones appeared as small discrete round dots, varying in size from pinhead to that of a hempseed, arranged symmetrically on both sides of the midline just above the symphysis. The histories showed no etiological factor, the concretions seeming to be normal results of old age. Between the ages of twenty and fifty they occurred in only five per cent. of the cases, while between fifty and ninety-three they were found in twenty per cent. In the second type the shadows occurred as good sized patches made up of conglomerations of the small ones. These appeared higher up in the pelvis, from 1.5 to 3.0 cm. above the symphysis. This type does not seem to be so definitely a senile condition, as it occurs in middle life. It appears to be caused by pathological changes. Forrsell concludes that his researches have demonstrated that the position, arrangement, form, and density of prostatic concretions are very characteristic, and that, as a rule, the differentiation from other concretions within the pelvis is possible. Also, that prostatic stones, both normal and pathological, are much more common than previously thought, and that they can be discovered by a careful *x*-ray examination.

Deutsche medizinische Wochenschrift, June 3, 1909.

The Treatment of Gastric Ulcer.—W. V. Leube describes his routine treatment of gastric ulcer. There are four cardinal points: (1) Rest in bed from one to two weeks. This relieves the pain and promotes healing. After the tenth day the patients lie down two hours after dinner. (2) Karlsbad water, a quarter liter lukewarm. (3) Application of a hot stupe or thermophore to the epigastrium. The stupe must be changed every fifteen minutes and kept very hot. He never uses stupes with bleeding ulcers, as they are apt to cause a recurrence of the hemorrhage. During hemorrhage ice bags are used instead. (4) Light diet of high nutritive value and easy digestibility. All four of these factors must be carried out. By this routine he has reduced his mortality from 13 per cent. to 2.5 per cent., and finally to hardly 0.5 per cent. In severe hemorrhagic cases Leube puts the patients to bed, gives one dose of 30 minims of a 1-1000 solution of suprarenal extract, places an ice bag on the abdomen, and quiets the stomach with bismuth and a hypodermic injection of morphine. He does not believe in giving eggs and milk to bind the acid. He says it simply causes the secretion of more acid, and produces peristalsis. He reports the following results: In 547 non-hemorrhagic cases 90 per cent. cures, most of these being effected in from four to five weeks, no deaths; in hemorrhagic cases 90 per cent. cures and 2.5 per cent. deaths. For the first few days after a hemorrhage he gives no food whatever by the mouth.

Chronic Chorea Following Migraine.—Schabad reports the case of a woman of fifty who since she was twenty-two had suffered from severe attacks of migraine. At forty, when three months pregnant, the migraine ceased and was replaced by a marked chorea, which lasted during the remaining six months of pregnancy. After the birth of the child the chorea ceased and the migraine returned. For the past fifteen months the chorea had returned and the migraine had again left. The case is either one of chorea adultorum permanens or Huntington's chorea. The author is not able to determine which. Migraine is supposed to be a vasoconstrictor spasm of the cerebral arteries, but various pathological findings have been reported as effusions of blood in the brain, softening of the brain, hemorrhagic pachymeningitis, and thrombosis of the internal carotid artery. Almost the same lesions are found in Huntington's chorea. This probably explains the change in the symptoms from migraine to chorea and back again.

Book Reviews.

THE PROBLEM OF AGE, GROWTH, AND DEATH. A study of Cytomorphosis, based on Lectures at the Lowell Institute, March, 1907. By CHARLES S. MINOT, LL.D. (Yale, Toronto), D.Sc. (Oxford), James Stillman, Professor of Comparative Anatomy in the Harvard Medical School, President of the Boston Society of Natural History. Illustrated. New York and London: G. P. Putnam's Sons, 1908.

THE author of this most interesting and thought-stimulating work sustains throughout his thesis the paradox that the cell changes characteristic of old age begin at birth and advance most rapidly in the early years. Senescence, he says, is at its maximum in the very young stages, and the rate of senescence diminishes with age. Life to him is like a race by an untrained contestant; the greatest speed is made at the outset and, as the struggle is prolonged, the pace grows slower and slower until, as the goal is approached, the progress becomes a walk, and finally a weary dragging of the limbs. Dr. Minot has little use for Metchnikoff's well-known theory of the rôle of the macrophage in the destruction of the noble cells, but looks upon senility as a result of the natural and inevitable cell changes; that is to say, upon the increase of protoplasm and differentiation of the cells. Conversely, rejuvenation depends upon an increase of the nuclei. These theorems are well sustained by plausible argument and experiment, but the proposition is too startling to be accepted unreservedly without more convincing proof than the author has been able to bring forward, and the reader is stimulated to search for the fallacy which he feels must be concealed somewhere in the argument. Old age and natural death are not always and invariably the consequence of differentiation of cells, for they occur, Weismann to the contrary, in unicellular organisms in which no differentiation takes place. In the metazoa, moreover, it is not the most differentiated cells, those of the nervous and muscular systems, for example, that show the first and most marked degenerative changes in old age. Furthermore, the being starts from an old and differentiated cell, or from the union of two differentiated cells. This is not the place for, nor would the reviewer attempt, a refutation of Prof. Minot's theories. We merely mention a few of the objections that would naturally occur to any one; they do not necessarily invalidate the author's argument, and we would advise every one interested in the great problem of senescence—and who is not?—to read this fascinating book and formulate his own objections to the theory and offer a better one, if he can.

LE DIABÈTE SUCRÉ. Par R. LÉPINE, Professeur de clinique médicale a l'Université de Lyon; Correspondant de l'Institut Associe de l'Académie de Medicine, etc. Paris: Felix Alcan, Editeur, 1909.

THE work of Claude Bernard, terminated only by his death in 1877, did much to clear up by experimental methods the conditions under which glycogen is formed in the liver, and also many of the immediate causes of the appearance of glucose in the urine. The carrying on of the problems which Claude Bernard laid down fell more to the Germans than to his own countrymen, and much of our present knowledge of the peculiar disorder of metabolism which we call diabetes is due to the studies of Voit, Seegen, Külz, Minkowski, Naunyn, and von Noorden. The writer of this volume has been the exception to this rule, and in the last twenty years has done much, both from the clinical and from the experimental side, to advance our knowledge of diabetes and to save France from the reproach that she had forgotten Claude Bernard. Lépine's interests have been concentrated rather more especially on the nature, amount, and transformations of the sugar found in the circulating blood; but there are few phases of the subject of diabetes to which he and his pupils have not made contributions. This book, therefore, carries the authority of an ingenious experimenter, tempered by the shrewdness of the experienced clinician. That he appreciates, in addition, the work of others, is shown by the enormous number of footnotes, the majority of which refer to German writers. After an historical introduction the writer considers the sugars of normal blood and the changes of the carbohydrates in the intestine leading to final formation of glycogen and the deposition of this latter substance in the liver and other organs. Nearly two hundred pages are devoted to a consideration of the various types of non-diabetic glycosurias. The writer then turns to his main subject: diabetes, its symptoms, complications, course, diagnosis, and treatment. Almost every page is suggestive, but the experimental part is stronger than the clinical. Perhaps the portion which is apparently the least helpful is that on treatment, in which general principles are given, but not the rigid, almost military regulations; and the long tables of foods, permissible or not, with which we are familiar in the treatises of von Noorden and other German writers are absent. It is possible that Lepine feels that every case must be treated on its own merits, and that the setting up of hard and fast rules does not result in as intelligent a treatment of the patient as does leaving the physician free to exert his own judgment. The question of acidosis and coma is fully discussed, and, as in most recent publications, the use of infusions of sodium carbonate is suggested, with the observation that the results are not very encouraging. The volume is a very valuable contribution to the literature of diabetes.

A SYSTEM OF DIET AND DIETETICS. Edited by G. A. SUTHERLAND, M.D., F.R.C.P. London: Oxford University Press, 1908.

THIS treatise on dietetics is a combination of the personal experiences of men who have seen enough of sickness to make their opinions of value. The first part of the book is taken up by a discussion of the scientific aspect of dietetics, written withal in simple words, explaining the details where necessary, but keeping to main ideas enough to avoid confusion. The chapter on experimental work on diet, by E. I. Spriggs, gives many valuable tables showing the fuel value of the commoner kinds of food in a way which makes the tables of practical value. The essentials of the various diet cures and the composition of the more common proprietary foods are discussed briefly but thoroughly. The second part of the book considers the proper diets in the various diseases. Each author tells what he has found of the greatest value in his own practice in some detail, and also touches lightly upon the various methods of others, where those methods seem worthy of mention. The work is eminently practical. The articles are written in a simple, straightforward style, which makes them interesting reading and gives one quickly and accurately the essentials of the authors' opinions as to the best way to feed patients suffering from various diseases. The book contains many tables, dietaries, and recipes, which are so inserted as not to interfere with the text or confuse the main thoughts of the authors. It is well printed on dull paper in large, clear type, with a good margin. Heavy-faced type is used in the text instead of headings or marginal notes. The book is, taken all in all, a good addition to a library, and is to be recommended to anybody who wishes a safe and sane exposition of the principles of dietetics in disease.

DIE PARENCHYMATÖSE HORNHAUT-ENTZÜNDUNG. Von Dr. KARL HOOR, o. ö., Professor der Augenheilkunde an der konigl. ung. Universität in Budapest. Halle a. S.: Carl Marhold, 1909.

THIS brochure is a complete critical review of the subject of interstitial or parenchymatous keratitis, occupying 124 pages of text. Many authors have been consulted. A bibliography occupying 21 pages is appended. There are no illustrations.

GENERAL MEDICINE. Vol. I of the Practical Medicine Series. Edited by FRANK BILLINGS, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. SALISBURY, A.M., M.D., Professor of Medicine, Chicago Clinical School. Chicago: The Year Book Publishers, 1909.

THE review of the literature pertaining to general medicine and its progress in 1908 is well presented in this small book of about four hundred pages. The first half of the book is given over to the consideration of the diseases of the respiratory organs—the first hundred pages having to do with pulmonary tuberculosis. Then follow the diseases of the circulatory organs, infectious diseases, diseases of the ductless glands, metabolic diseases, and diseases of the kidneys.

HOW TO NURSE SICK CHILDREN. By CHARLES WEST, M.D. London: Longmans, Green & Co., 1909.

To those interested in the care of children the name of Charles West, the founder of the first and greatest of the world's children's hospitals, is attractive. This little book, written many years ago and sold for the benefit of the young and struggling Great Ormond Street Hospital, is welcome in its new edition. It is full of useful hints to the nurse who attends a sick child, both as to symptoms to be observed and minor details of care. It takes up various systems, as the brain, lungs, and stomach, separately, and gives good advice to the nurse about each disease. The book should be made a part of the required reading in every training school.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 20, 1909.

Dr. John A. Wyeth in the Chair.

This meeting was held under the auspices of the Section on Laryngology and Rhinology.

Amendment to the By-Laws.—A motion to amend Art. XIII, Sec. 14, to read: "Any Fellow, Associate Fellow, or other person violating the rules of the library shall, in the discretion of the Committee on the Library, subject to approval of the Council, be suspended from the privileges of the library for a period of time, and shall be liable to a fine," was carried.

Presentations.—Mrs. William T. Bull presented to the Academy of Medicine a bust in bronze of her late husband. The bust was Dr. Bull's last gift to his wife. The sittings for it were made after the operation, when he had great bodily suffering.

Dr. Virgil P. Gibney accepted the gift in behalf of the Academy.

The American Gynecological Society presented a bronze medallion of Ephraim McDowell, who performed the first ovariotomy a century ago. It was moved and carried that a vote of thanks be sent to the Society for the gift.

Clinical Diagnosis and Operative Procedures, from the Standpoint of the Laryngologist.—Dr. Chevalier Jackson of Pittsburg gave a lantern slide demonstration of operations for intralaryngeal carcinoma.

Microscopical Diagnosis of Intralaryngeal Growths from a Practical Standpoint.—Dr. Jonathan Wright said that the surgeon and microscopist could only hope to be mutually helpful, and, above all, helpful to their patient, by the fullest and frankest interchange of information and opinion. The opinion of the microscopist as to the meaning of a cell or two in his shred of tissue might hinge upon the question of whether the patient had been thoroughly treated for syphilis. The contingencies were innumerable where the clinical history was a deciding factor in the microscopic diagnosis. Every one who had had much surgical experience knew of the spontaneous recovery from tumors pronounced malignant by the microscopist, as well as by the clinician. The clinician was always modest enough to acknowledge his own fallibility, but he thought the microscopist should have known better. They were both fallible, yet it was becoming clear from animal experimentation with cancer that they were fallible because some thirty or forty years ago a slip in logical reasoning occurred. It was observed that *most* men afflicted with tumors of a certain tissue synthesis died from their continued growth. They jumped at the conclusion that *all* men died who had tumors of that particular synthesis. It was dogmatically asserted that structure, the apposition of certain kinds of matter in a certain arrangement, was an expression of malignancy. Forgetful of the fact that in the cancer question there were two sides, one the invasion of the malignant cells and the other the resistance to it, they had ascribed to the clinician and the microscopist the errors inherent in the fallacy presented by a faulty syllogism. This plainly arose from a study of structures in advanced cases of cancer. Structure was not an infallible guide, and really all the microscopist had any right to say in any given case was that the tissue presented the appearance usual in cases which ended fatally. Now, while this might seem amply sufficient, on account of the rarity of cases recovering at the stage where reasonable doubt of diagnosis was admittedly very slight, it was a different matter entirely when they came to deal with a small excrescence on the vocal cord. At the very outset such a cancer caused symptoms that could not be concealed, and no set of men saw cancer at so early a stage histologically as the laryngologists. It naturally followed that when the microscopist was given a paring from such a growth he more frequently fell into error if he said that it was going to run a fatal course if left to itself. The structure was the same, but the result, the clinical prognosis if the tumor was left to itself, manifestly must be more uncertain. He hoped to convince them how extremely fallible the microscopist dealing with laryngeal growths was. Structure, and especially the nascent structure of tumors, was not a safe criterion for prognosis.

The Treatment of Cancer of the Larynx from the Point of View of the General Surgeon.—Dr. George Emerson Brewer read this paper. Cancer of the larynx, whether considered from the point of view of the laryngologist or the general surgeon, presented one and the same problem. Can the victim of this dread disease be subjected to any form of treatment which would offer a probability or possibility of cure, or, if not, could anything be done to mitigate his sufferings? Not one authentic case of carcinoma of the larynx was ever cured, except by early surgical removal of the disease. Four methods of radical surgical treatment had been proposed. (1) Intralaryngeal removal; (2) thyrotomy, allowing exposure of the diseased area, and removal of the lesion with subsequent closure of the laryngeal cavity; (3) partial laryngectomy; (4) total laryngectomy. The almost uniformly disastrous results which have followed intralaryngeal removal of the growth had led to its general condemnation and abandonment. Since Semon's masterly presentation of the subject in America in 1904, thyrotomy or laryngotomy was an operation that had steadily grown in favor, and was to-day the operation of choice in early cases of intrinsic cancer. He said he could do no better in this connection than to quote Semon's advice regarding indications. "All intrinsic cases of cancer, not too extensive, not too near the posterior wall, and not infiltrating the cartilages, ought to be treated by thyrotomy." Partial or hemilaryngectomy was indicated in cases of unilateral intrinsic disease, in which the lesion extended too far backward to promise a favorable result by simple thyrotomy, or when there was reason to believe that the perichondrium or cartilage was involved. Although the indications for this operation were not as frequently encountered as for thyrotomy or total laryngectomy, it had the great advantage that it preserved the normal oral or nasal respiration, and not infrequently allowed the patient to retain a speaking voice of fair quality. The cause of the immediate mortality of total laryngectomy was recognized by all careful observers to be, first, the occurrence of inhalation pneumonia, and, second, the extension of the infection from the wound downward along the cellular planes of the neck to the mediastinum. The first notable advance in technique was that proposed by Gluck in 1881, who suggested and practised prophylactic resection of the trachea and implantation of the distal extremity through a button hole cutaneous wound just above the suprasternal notch, thus cutting off all connection of the air tube with the wound, and preventing thereby the entrance of pharyngeal mucus and wound secretion. In 1908 Gluck reported 128 operations; 20 patients were alive and free from recurrences at the end of three years, or a trifle over 15 per cent. Two operations had been advised to diminish the suffering in advanced and inoperable cases—tracheotomy and the starvation treatment, recommended by Dr. Dawbarn. Dr. Brewer said that he had performed thyrotomy sixteen times, with one death; of these sixteen cases only seven were for undoubted carcinoma. His experience with total laryngectomy was limited to eleven cases; of these, five died as the result of the operation, and six recovered. Dr. Brewer's technique in total laryngectomy was as follows: Under general anesthesia a median incision was made extending from the cricoid to the sternal notch. The isthmus of the thyroid

was doubly ligated and divided. The separated edges were pushed to each side and the trachea freely exposed. A low tracheotomy was then performed and the canula introduced, after which the upper part of the incision was united with silk worm gut sutures, and the peritracheal spaces generously packed with iodoform gauze both above and below the cannula. The word was dressed and the patient placed under a tracheotomy tent, into which a small amount of steam is introduced by means of a croup kettle. The external opening of the tracheal cannula was constantly covered with four or five layers of gauze wet in warm boric acid solution, with a view of filtering the air which entered the trachea. About ten days after the preliminary operation the secondary operation was undertaken. Under chloroform anesthesia an incision was made from the body of the hyoid downward to the upper limit of the former cut. From the upper extremity of this incision two lateral incisions were made in an upward and outward direction, extending to the anterior borders of the sternomastoid muscle. The two triangular flaps were turned outward, the sternohyoid muscles divided just below their attachment, and the sternothyroids detached from the cartilage. The two superior arteries were ligated. The superior laryngeal nerves were cut and all lymph nodes removed. The attachment of the inferior constrictors were next divided and the posterior surface of the cricoid partly separated from the esophagus. When the larynx was thoroughly skeletonized the trachea was severed just below the cricoid and its distal extremity immediately packed tightly with gauze. The finger was next introduced into the upper or laryngeal segment of the tube, and the larynx gently raised from the esophagus. When the larynx was completely separated from the esophagus the tips of the thyroid cornua were divided, the thyrohyoid membrane incised, and the larynx completely removed. The pharyngeal wound was then packed with gauze. The oval pharyngeal wound was next tightly closed by two layers of suture. After closure of the pharyngeal opening the entire upper wound was temporarily packed with wet formalin gauze, while the tracheal stump was prepared for closure. This was accomplished by removing redundant tissue above the canula opening, dissecting out or destroying with cautery the mucous membrane, and packing firmly with iodoform gauze above the tube. A rubber feeding tube was then introduced through the left nostril into the esophagus and secured. The wounds were next united above with the general gauze packing about the tube.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 29, 1909.

DR. JOHN O. POLAK IN THE CHAIR.

A Case of Ureterovaginal Fistula Cured by Vaginal Operation.—Dr. HENRY DAWSON FURNISS reported this case, a woman, sixty-three years of age, who had had one child. In December, 1906, she bled for one week, and then had no more bleeding until the following November. On December 7, 1907, a hysterectomy was performed for the removal of a carcinomatous uterus. The left ureter was tied, and for a day and a half there was complete anuria. Three weeks after the operation her bed was found wet with urine, and from that time on the urine escaped continuously. She was cystocoped and found to be suffering from a catarrhal cystitis. The catheter could not be made to enter the left ureter. The cystitis was treated, but the constant flow of urine continued. A fistula was sought, using the methylene blue method, but none could be found. Three large braided silk sutures which were introduced at the time of the operation were found. He saw the patient several times, but never saw any urine coming from that ureter into the vagina. The patient was put in the knee chest position after giving methylene blue by the mouth. The vagina was then tamponed, and he was able to detect the ureteral fistula by the stain. A filiform bougie was passed and the patient was made to sit on a vessel for two hours in order to collect the urine passed through the fistula. It was then shown that the left kidney was secreting less urine than its fellow. There was a ureterovaginal fistula which required operation. As the patient would not consent to an abdominal operation, the vaginal operation was performed. The ureter emptied into the vagina high up. A vesico-vaginal fistula was made in front of the ureteral opening. The mucous membrane of the vagina was denuded anterior to the vesicovaginal fistula and posterior to the ureteral fistula, the areas of denudation coming together laterally. By a transverse line of sutures (silkworm-gut and catgut) the denuded areas were brought together so that the ureterovaginal fistula, with a small portion of intact vaginal mucous membrane around it, was turned into the bladder. A retention catheter was used for five days. There had been no leakage since. There was practically an atrophied kidney on that side. The filiform bougie passed but one-half inch into the meatus of the ureter.

Dr. JAMES N. WEST said that he thought the method used by Dr. Furniss was a very ingenious one, and one which would give excellent results in such cases. It was simple and comparatively easy to bring together the walls of the fistula as had been shown. Dr. West asked what the operation was during which the ureter was divided.

Dr. Furniss replied that it was an abdominal hysterectomy for carcinoma of the body of the uterus.

Dr. West said that he could see no excuse for tying off the ureter at that point. In carcinoma of the uterus the cervix was of normal size, and one need not come near the ureter. Again, the braided silk sutures passed away. To-day few used silk sutures for such operations, but only catgut.

Vaginal Cysts and Their Histology.—Dr. GRACE PECKHAM MURRAY presented this paper. She said that vaginal cysts were exceedingly rare, and that the case she reported was the only one that had come under her observation. The vagina was, as a rule, free from neoplasms of all kinds. She could recall only one case of a tumor in the vagina having its origin in the vagina, and that was a case of polypus. The case reported was that of a woman thirty years of age, who was seen at the Post Graduate Hospital in 1907. She had been married six years, had two children and no miscarriages. The older child was six years old and the younger one two years. She had menstruated at the age of fourteen, and had always been regular. After each period she had some leuchorrhea, more since her children had been born. She presented herself at the hospital because of a growth in the vagina about the size of a hen's egg. The tumor was found to be elastic, with slight fluctuation, and was situated between the cervix and the vulva, its base being about two inches in diameter. The cervix was small and the uterus retroverted. The patient entered the service of Dr. James N. West at the Post Graduate Hospital for operation. The cyst was shelled out, the cavity obliterated and the wound closed. An Alexander operation was also performed. The patient was discharged with her uterus in the normal position. Vaginal tumors were of little interest except from the standpoint of their origin. Every case found should be presented and its histological appearance studied. The diagnosis was a simple matter, although they should be carefully differentiated from hernia in the vagina. From a surgical point of view, vaginal cysts were of little importance. When the tumor was situated in the anterior wall, care should be exercised not to injure the bladder. These cysts were usually unilocular and situated in the anterior wall. Cysts of the lateral wall were very rare.

These tumors were of very slow growth. In the case reported there had been no change for several months; many years were required before the tumor reached the size of a hen's egg. These cysts usually contained a fluid which might vary in solor and consistency, and all authorities seemed to agree that the fluid contents of these cysts were without particular significance. Casts had been described as traumatic in origin, as being superficial, and as being deep; it had been though that the vaginal mucous membrane was incapable of producing cysts of such a size and that any cyst the size of an orange must originate outside the vagina. In 1887 the theory was advanced that these cysts were embryonic in origin, and many thought the problem was solved. The text books of the day dismissed the subject quite readily; some said the vagina had glands, and some that the vagina had no glands, while others stated that the glands of the vagina were scanty. It seemed surprising that there should be such a conflict of opinion in regard to this matter. One pathologist had taken thirty specimens, and took six pieces from different parts of the vagina, and in only one instance did he find anything that appeared like glands. His conclusion was that normally the vagina was glandless. Dr. Murray was of the opinion that these cysts arose from the vagina itself, and were retention cysts.

Dr. James N. West said that the cysts of the vagina that he had seen were situated in the anterior wall and extended to the broad ligament. They had been regarded as the fetal remains of the ducts of Gärtner. They extended far up in the broad ligament, and were quite hard to remove. The only cyst he had ever seen situated in the posterior wall was that reported by Dr. Murray. He had seen small cysts arranged in little rows resulting from injury to the perineum high up. These cysts, when of large size, were of practical interest only from the obstetrical point of view, causing considerable resistance to the descent of the head. Dr. West thought the conclusion regarding the origin of these cysts had been well taken so far as he had followed the subject in the literature. These cysts were interesting from a scientific point of view, from their rarity, and from their location. Their removal offered no difficulty as a rule.

Dr. Dinkelspiel said that during pregnancy these cysts increased rapidly in size. Personally, he was familiar only with the retention cyst of the Gärtner duct.

Dr. C. Clarence Sichel said that he had seen three or four vaginal cysts, and that one was now under his observation. This was situated in the posterior vaginal fornix, high up, and dated from the birth of the last child.

Dr. Murray, in closing the discussion, said that there had been described in literature one or two cases in which small cysts followed others, and they were supposed to arise from the remains of Gärtner's duct. It was her opinion, however, that cysts situated high up in the broad ligament were of embryonic origin. What was most interesting was whether or not they had to deal with a true vaginal cyst, and her paper was offered as a contribution to this much discussed subject regarding the origin of these cysts. One of the noted pathologists, Stokes, took the position that there was no such a thing as a vaginal cyst of considerable size; such a tumor must come from structures other than the vagina.

Dr. James N. West said that he had a case under observation with a cyst just to the right and beneath the urethra, as large as a pigeon's egg; it was on the anterior wall, quite low down. The woman was married, but has never borne children. It was situated within one inch of the meatus urinarius, and did not run in the direction of the ureter. Nothing had been done to it thus far.

The Cost of Typhoid Fever.—It is estimated that typhoid fever costs the United States $90,000,000 annually.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 19, 1909.

The President, Dr. Robert T. Morris, in the Chair.

Cerebral Affections of Nasal Origin.—Dr. W. Freudenthal, in this paper, said he would limit himself to those infections of the brain of nasal origin which might be called primary, namely, those following empyema of any of the accessory sinuses. While cerebral affections of otitic origin were comparatively common, a careful search of medical literature showed the records of very few of nasal origin. This the speaker attributed not so much to their rarity as to the fact that their true source of infection was so commonly overlooked. Speaking of the modes of infection, Dr. Freudenthal said that many years ago Zuckerkandl described defects in the posterior wall of the frontal sinus, in some instances only the mucosa and dura separating the sinus from the cranial cavity. In such a case, if an empyema of the frontal sinus developed, extension of the infection to the brain might readily occur. Similar defects had also been observed in the walls of the ethmoidal and sphenoidal sinuses, and this should serve as a warning against rough curettage, especially in the sphenoidal sinus. In cases in which there was no bony defect the infection might result from direct continuity. First, the mucous membrane became diseased, followed by a subperiosteal abscess. The necrotic bone then produced an extradural abscess, followed by meningitis, cerebral abscess, and sinus thrombosis. There were also cases of metastases where the bone was not affected, only the discoloration of the bone proving that the process had penetrated there. Infection from the nasal cavity to the brain might also be the result of an anastomosis of the veins of the mucosa of the frontal sinus with those of the dura: when such a vein became infected the infective material was readily carried into the brain. It was probable that the infection might also travel through the lymphatics or along the sheath of the olfactory nerve through the lamina cribrosa. Dr. Freudenthal then reported in detail three cases of brain infection of nasal origin that had come under his personal observation.

Dr. Robert C. Myle showed a cross section of a skull in which the routes of infection between the accessory sinuses of the nose and the brain could be clearly demonstrated. It was astonishing, he said, that cerebral affections of nasal origin, both from disease and from operative interference, were not of much more frequent occurrence. In spite of the comparative impunity, however, with which we cut out nasal tissue and entered the frontal, sphenoidal, and various other accessory sinuses, statistics were accumulating showing that resulting brain complications were not as rare as we formerly supposed. Personally, he could recall two cases in which the brain infection occurred directly. One was that of a man with chronic frontal sinus disease, for the relief of which operation was refused. Subsequently, symptoms of meningeal irritation developed, and these persisted for many months. Finally the man consented to an operation, and on the very eve of this he suddenly developed violent intracranial symptoms and died. In the second case, following a grippal infection, and without evidence of any sinus disease, the patient developed a fistulous tract which burrowed along the outer wall of the antrum, extending inward along the inferior turbinal, and subsequently resulting in fatal meningeal symptoms. In dealing with sphenoidal sinus disease, Dr. Myles said he always exercised great care in the removal of that part of the diseased wall adjacent to the nose, while he never curetted the upper wall of the cavity on account of its proximity to the brain. With the exception of a severe hemorrhage in one instance, he had never seen

any injurious effects follow operations on the sphenoidal sinus. The comparative rarity of cerebral affections of nasal origin, the speaker said, could be partly traced to the fact that the dura mater covering the sinus walls was very resistant to the inroads of infection. In addition to the routes of infection mentioned by Dr. Frendenthal, Dr. Myles said he had seen and known of cases where the infection occurred through the posterior part of the vomer from adenoid operations. In such cases the infection usually involved the sphenoid and was associated with cavernous sinus thrombosis. Dr. Myles also presented a chisel which cuts outwardly and away from the cerebrum, and which he had found extremely useful for cleaning the several sinuses when their degenerating contents threatened to infect the meninges and the brain.

Dr. Lewis A. Coffin said the cerebral affections of nasal origin included cerebral abscess, the various types of meningitis, pachymeningitis, and the meningitis of congestion or serous, and Tobert had spoken of a septic type. The question of the modes of infection was still unsettled. Undoubtedly, infection took place from contiguity, when the inner plate of the sinus became diseased or necrotic. Indirect infection probably took place through both the lymphatic and blood channels, but of the former we had no proof. The reader of the paper spoke of the dangers attending curettage of the sphenoidal sinus. Personally, Dr. Coffin said, he would hesitate to do a radical operation on the frontal and ethmoidal cells and leave the sphenoidal infection behind. Many cases of death, he believed, had resulted from just that procedure, namely, stirring up the infective germs to greater activity and leaving behind the best possible media for their development. After a thorough Killian operation he did not see how there could be any danger of recurrence, because the frontal sinus was practically obliterated and there could be no further infection unless it took place through the cicatricial tissue. In cases that demanded a radical operation on the frontal sinus he was opposed to any preliminary operative work on the nose. He agreed with Dr. Myles that there was no more danger in going into the sphenoidal sinus than there was in going into the ethmoidal or frontal.

Dr. W. Sohier Bryant said that Dr. Frendenthal's cases indicated the great danger of deferring a radical operation in severe cases. In spite of the fact that nasal infection was more than ten times more frequent than aural infection, brain infection from ear disease was at least three or four times more frequent than from nasal disease. This was probably accounted for by the fact, as had already been suggested, of the case with which nature drained the nasal cavity and its accessory sinuses. Dr. Coffin had emphasized the importance of thorough operation and a one stage operation, and the speaker said that he heartily concurred with both of these suggestions. In acute cases, with cerebral symptoms, an operation was indicated at the earliest possible moment in order to save the life of the patient. The importance of the nasal cavities as a source of intracranial infection was now generally recognized, but the frequency of brain involvement from nasal infection in so called general diseases was not as commonly recognized. Cerebrospinal meningitis, for example, was always secondary to nasal and accessory sinus infection. We might, therefore, say that cerebrospinal meningitis was of nasal origin. In other diseases the fatal lesion might be located in the brain, and might be secondary to nasal infection. Usually in such cases the general practitioner overlooked the local significance of the cranial symptoms. Dr Bryant said he had recently observed a case which had been diagnosed as "lobar pneumonia." An autopsy revealed that the cause of death had been purulent lepto meningitis of both hemispheres, consequent on a purulent pansinusitis. The lobar pneumonia was present, but was only a minor part of the pneumococcic infection.

Dr. Frendenthal, in closing, speaking of brain complications resulting from frontal sinus disease, said that this was not always due to pressure alone, but to the virulence of the infective organism. As to the lymphatics serving as an avenue of infection from the nose and its accessory sinuses to the brain, he did not see why this should not be so here as elsewhere in the body. He thoroughly agreed with Dr. Coffin that when once a radical operation had been decided on no minor preliminary operations should be attempted. Replying to Dr. Bryant's statement that cerebrospinal meningitis was always secondary to nasal and accessory sinus infection, he said that this was not borne out by the investigations of a German writer, whose name had escaped him, who had made many autopsies during an epidemic of cerebrospinal meningitis and had found that the infection took place through the retropharynx.

Some Technical Difficulties in Operations for Hypospadias and Other Urethral Affections.—Dr. Carl Beck, preceding the reading of his paper, showed three cases of hypospadias treated by his method of forward dislocation (distention) of the urethra. One—a child of eleven months, who suffered from the penile type—underwent the operation four weeks ago and showed a perfect result. No sign of incurvation was noticeable, the urine was projected in a natural stream, and the mobility of the penis was normal. The other two patients presented were brothers who were operated upon by the same method six weeks ago. The elder brother, who was five years old, suffered from an extreme scrotal type of hypospadias, in which, as a rule, the extensibility of the urethral stump was too limited to permit of the distention method. Still, in suitable cases it was well worth trying. In this case it gave a perfect result as regarded micturition, the stream of urine now being straight, whereas previously the patient always soiled his clothing. The small size of the penis and the overhanging of the scrotal folds were defects that still remained. It was hoped, however, that greater mobility of the penis might be obtained by some future operation. The case of the other brother was unique in that it represented the youngest patient that had ever been operated on for hypospadias. At the time of operation the child was nineteen days old. The youngest child that Dr. Beck had previously operated on was five months of age. In this child of nineteen days the penis was somewhat larger in proportion than that of his brother, and his chances of further development of the organ were better. In discussing the advantages of an early operation in these cases, Dr. Beck said that, aside from the better chances of further development, the penis, during the infantile period, was less inclined to erection than later on, when excessive rigidity might produce undue tension of the sutured area. Again, there was no better protection for the wound area than the diaper, which the baby could not displace; in other words, it would not interfere with the wound with its hands which an older child was apt to do. Even tying the hands of a nervous child to the bedstead was no absolute guarantee, aside from the apparent cruelty of such a procedure. Instead of asking the question, "When to operate," one should ask "When not to operate." The operation was more delicate in infants than in older children, and with that point in view Dr Beck showed a special set of instruments which he had made for him for the purpose.

Dr. R. Pfister, after referring to the great annoyance that this condition of hypospadias caused both parents and children, said that by the method of operation described by Dr. Beck we could promise a good result almost with certainty, and without resulting fistula, because the urethra was not opened nor injured, and even if the operator was unfortunate enough to meet with such an accident in these young patients a fistula would not occur if the flap was sewn up very carefully.

Dr. Samuel Lloyd said that, while the technique of the

procedure described by Dr. Beck was excellent, he could scarcely bring himself to believe that an entirely satisfactory operation for hypospadias had been developed. In connection with this condition we had to consider the development of the penis in the future, and in extreme cases it seemed utterly impossible to remedy the defect so that the penis would be straight and that no incurvation would occur during erection. While brilliant results were occasionally obtained in operating on these patients, more frequently the results were utterly unsatisfactory. The speaker recalled one case of penile hypospadias in a ten-year-old boy upon whom he operated by the method described by Dr. Beck with a practically perfect result, while in a second case the operation proved a complete failure, due to persistent erections and the tearing out of the stitches. Referring to catheter drainage, the speaker said he had found it very difficult to keep the catheter in place, and an irritable urethra would not tolerate its presence. Personally, he was inclined to favor a perineal urethrotomy instead for drainage purposes; he had done this in several instances with satisfactory results. The main objects in view were to lengthen the penis and avoid insurvation, and to attain those ends he believed that the combined operation, distending the urethra as far as it would go, and the flap method afterward, would give the best results.

Dr. Edward W. Peterson said that in one case of hypospadias of the penile type he did the Beck dislodgment operation with excellent results. Personally, he believed that an operation to correct a penoscrotal or perineal hypospadias was one of the most difficult that fell to the lot of the surgeon—even more so than cleft palate. In the last case upon which he operated he freed the urethra and allowed it to retract, leaving a strip of skin to serve as a roof for the urethra, and forming the floor from a scrotal flap. Drainage was made through a perineal puncture.

Dr. Martin W. Ware said he thought the operation of mobilization described by Dr. Beck was the very best one we had for the treatment of hypospadias, certainly of the balanic type, but when it came to the penoscrotal type, each case had to be judged on its individual merits. In doing this operation the artificial meatus was apt to grow smaller, and the question arose whether to make the incision in an anteroposterior or lateral direction. A certain amount of redundant skin should be left surrounding the orifice, which could afterward be utilized. The great drawback to the success of all these operations were the erections, which were very apt to occur and undo the work of the surgeon, and to overcome these Dr. Ware said he was in favor of using opiates freely, particularly in the form of suppositories. The indwelling catheter he had always looked upon as a possible source of infection and of pressure on the newly formed meatus. In preference to it he favored perineal drainage, and on several occasions resorted to puncture of the bladder itself.

Dr. Beck, in closing, said he made no claim that he had cured any case of extreme perineal hypospadias in the full sense of the word, but he did claim that his method of forward dislocation of the urethra cured with absolute certainty any case of the balanic or penile type. He had never seen incurvation follow any of his operations on such cases. In the extreme perineal type the distention method should not be attempted except in combination with other plastic procedures. But even if we only gave the patients suffering from the scrotal variety the ability to pass a straight stream of urine we were doing much to add to their comfort. He was fully in accord with those who believed that the last word in regard to the ideal treatment of a case of scrotal or perineal hypospadias had not yet been spoken.

Ten Consecutive Cases Illustrating the New Point in Appendix Diagnosis.—Dr. Robert T. Morris made a brief report upon ten consecutive cases in which the relative value of the new diagnostic point, when there was a question of appendicitis, was concerned. The point consisted in an area of hyperesthesia at the site of the right group of lumbar ganglia, about an inch and a half to the right of the navel. The ten consecutive cases were the last ten seen before the meeting, and were fairly representative. They were cases in which the question was definitely decided. A number of other cases in which the point was of greatest consequence were not included, because they did not go to operation to give opportunity for examining the appendix. It was in fibroid degeneration of the appendix that the new diagnostic point was of most value, and as these cases were often not subjected to operation, none happened to be among the ten consecutive cases upon which Dr. Morris made the report. In the series there were two cases of bubonocele sent for operation for appendicitis. Absence of hyperesthesia at the site of the right group of lumbar ganglia led to the discovery of the bubonoceles. The point was of value in these two cases in a negative way. There were three cases of acute appendicitis in which the point was not necessary as an aid to diagnosis because the other signs were sufficient. In two cases of interval appendicitis the point was helpful, because tenderness at the site of the appendix was absent, but was present at the site of the right lumbar ganglia. The point was absent in one interval case, and consequently of no value. It was misleading in one case of pelvic abscess of appendix origin, as both right and left groups of lumbar ganglia were hypersensitive. Dr. Morris had previously found that when both groups of ganglia were hypersensitive we could look to some pelvic organ rather than to the appendix for the source of the disturbance.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held May 10, 1909.

Dr. William Linder in the Chair.

The Treatment of Ophthalmia Neonatorum.—Dr. S. J. Levitt of Brooklyn read this paper. He pointed out the great importance of prophalyxis in dealing with this condition. Every pregnant woman with a mucopurulent or purulent vaginal discharge was to be appropriately treated before delivery. When the infant was born, Credé's method of prevention was to be observed. The infant's eyes were to be cleansed with boiled water and then a drop of 2 per cent. silver nitrate solution was to be dropped into each eye and neutralized by a normal salt solution. Although ophthalmia neonatorum was produced by microorganisms, it was found that nitrate of silver surpassed the disinfectants in combating the infectious agents. Silver nitrate was especially poisonous to the gonococcus. It had also a mechanical effect, scarifying the superficial layers of the epithelium and causing their exfoliation, together with the gonococci that had penetrated into these layers. Microscopic examination of the conjunctival discharge was imperative as a necessary preliminary to the treatment. Gonococci were present on the conjunctiva even weeks after the discharge had ceased. Mild cases of nonspecific ophthalmia yielded easily to treatment, and were cured from a few days to two weeks, while gonorrheal cases ran a severe course and lasted from two to three months. The treatment was considered under three headings, as follows: Personal attention to the patient, application of cold in the first stage and frequent cleansing, and the application of silver nitrate and the after treatment. It was the physician's duty to see that his directions, which were explicitly given, were carried out faithfully by the nurse. This was a point that required particular emphasis, inasmuch as the little patient was frequently left in the hands of an irresponsible person. The eyes were to be examined daily

and the condition of the cornea particularly was to be noted. For this purpose the patient was to be placed in a good light, and the physician was to place the forefinger of his right hand on the supraorbital ridge, with the thumb of his left hand on the infraorbital ridge, care being taken not to press on the cornea. Before examination of the eye the pus was to be wiped away with a 1-10,000 bichloride or a boric acid solution. In the first forty-eight to seventy-two hours cold applications were to be applied by means of gauze pads placed on a block of ice and changed every minute. With the subsidence of the inflammation of the lids cold was to be discontinued. In mild cases the cold applications were to be applied for half an hour and then stopped for an hour, while in severe cases the applications were to be continuous. Frequent cleansing of the eye with 1-10,000 bichloride or saturated boric acid solution applied every ten or fifteen minutes, either by a pledget of absorbent cotton or an eye-dropper, was necessary. Every dressing coming in contact with the eye was to be immediately destroyed. As soon as the suppuration started, a solution of 1 per cent. silver nitrate was to be applied by the physician to the upper and lower lids. If the suppuration was very profuse, the application had to be done twice a day. In gonorrheal ophthalmia this treatment was to be continued at least six weeks. When the swelling of the lids and the secretion of pus had subsided, a tepid solution of 1-10,000 bichloride or boric acid was to be used every three hours. The silver application had to be applied every second or third day until the hypertrophy of the lids had entirely disappeared. If an infiltration or ulcer of the cornea existed, atropine 1 per cent. was to be instilled a few times a day.

Gonorrhea and Its Treatment.—Dr. VICTOR H. PENTLARGE of Brooklyn read this paper. He said that the subject was of such great scope that he would confine his paper briefly to the diagnosis and treatment of anterior urethritis, antero-posterior urethritis, and to the most common complications. The micriscope and the differential gram stain usually cleared up any doubt as to diagnosis. A so-called gonorrhea that cleared up in four or five days was frequently in reality a non-specific urethritis. There were many bacteria in the normal urethra which were identified with those found in the bladder and urethra during a cystitis. Cocci very similar to the gonococcus were found in the normal urethral excretions; but they were not decolorized by Gram's stain. Profuse urethral discharges containing many varieties of bacteria were caused by the injection of powerfully irritating solutions. There was a difference of opinion among authorities as to the differential diagnosis between acute anterior and acute antero-posterior gonorrheal urethritis. To a certain extent, the Thompson two or five glass test determined the diagnosis. If during the first few days of an acute anterior gonorrheal urethritis the patient passed five glasses of urine without interrupting the stream, and at least the last three glasses were found to be clear, then one had to deal with a characteristic case of acute anterior urethritis. In an acute antero-posterior infection all the glasses would be cloudy, at least for a time. After the subacute stage had been reached it would be found that the second and following glasses were clear. The explanation of this change was that as long as large quantities of mucus and pus were produced by the posterior urethra, just so long did this discharge pour into the bladder, making the bladder urine cloudy, but as soon as the secretion became moderate the internal sphincter muscle confined it to the posterior urethra, so that the first passage of urine swept the urethra clean, enabling the remaining urine to pass entirely clear. If at any time the patient had all of the glasses cloudy, it was necessary to treat his urethritis as a posterior urethritis to the very last. Many cases of antero-posterior urethritis ran their course without infecting the prostate and other adnexa, but the most frequent complication was the infection of the epididymis leaving the second place for the prostate. Epididymitis recurring simultaneously with an acute antero-posterior urethritis was not difficult to diagnose, but recurrent attacks of epididymitis occurring years after the original characteristic attack were frequently difficult to diagnose on account of the inability to find gonococci by ordinary means. The speaker had seen such cases in professional dancers and athletes. In such cases with no urethral discharge and with a clear urine, it was wise to make a guarded diagnosis, to be cleared up later when the subacute stage had passed. Indurations might be left in an epididymis following gonorrheal infection, which rarely simulated tuberculosis or syphilis. It was impossible to tell just how often during an acute antero-posterior urethritis the prostate was the seat of minute abscesses that gave rise to few or no subjective symptoms, but large fluctuating abscesses that gave rise to many unpleasant local symptoms were not very rare. With the diagnosis of urethral gonorrhea, and the presence of local symptoms, it remained for the examining finger to complete the diagnosis. It was characteristic that after the finger had passed the internal sphincter it came directly upon an obstruction apparently round, firm, highly sensitive, and hot, but only by means of force could fluctuation be determined. Gonorrheal rheumatism was a rare complication. The treatment of acute anterior gonorrheal urethritis was at all times to be as simple as possible, including rest and the internal administration of sandalwood oil or salol, although internal medication had no appreciable curative value. Locally 2 per cent. protargal solutions were to be given by the physician three or four times weekly throughout the entire course of the disease, while the patient himself was to make three injections daily of a ½ per cent. solution. The injections were to be made immediately after urinating, and were to be held from 5 to 15 minutes. The patient was to drink large quantities of tap water. This was frequently of curative value even when used alone. The "water-cure" did not suffice in posterior urethritis. Acids, spices, alcohol, tea, and coffee were to be avoided and constipation prevented. Injections were not to be used in acute stages when there was tenesmus. This was combated with rest, hyoscyamus, and potassium salts. The best treatment for subacute antero-posterior urethritis was by injection into the bladder of a ½ per cent. water solution three or four times weekly, with an anterior injection of 2 per cent. This effected a cure in from four to seven weeks, provided that careful treatment was carried out at home by the patient himself. For acute epididymitis the treatment was rest in bed, shaving of the scrotum and pubis, and immobilization of the testicles by means of adhesive straps. No local applications were necessary. The internal use of sedatives was called for. With the abatement of the pain, swelling, and sensitiveness the routine treatment for antero-posterior urethritis was to be begun. The treatment of prostatic abscess was somewhat similar, and in most cases the abscess ruptured into the posterior uretha if left alone. After this spontaneous evacuation the prostate rapidly regained its normal size and the treatment for antero-posterior urethritis was to be begun. The patients who did not follow orders, who indulged in coitus, alcohol, and excessive exercise, or who did not receive regular treatment, were the ones from whom were recruited the cases of chronic anterior-posterior urethritis, strictures, and periurethral lesions. For these were employed sounds, the instillation of 10 per cent. solutions of ichthyol in glycerin, 2 to 10 per cent. copper sulphate, or ½ to 2 per cent. silver nitrate solutions. The irrigation of the bladder with 1-10,000 silver nitrate, or ½ per cent. zinc sulphate, was useful after all gonococci had disappeared, and the mucous membrane remained congested or thickened.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

April 13, 1909.

ANATOMY AND EMBRYOLOGY.

1. Give the character of a vertebra.
2. Describe the skin and its appendages.
3. Hip joint: Describe it, naming variety, giving bones and ligaments.
4. Name the regions of the abdomen and give contents of any two.
5. Describe the brachial artery and name its branches.
6. Describe the inguinal canal. Wherein does an artery differ from a vein?
7. Give origin and insertion of triceps muscle.
8. Describe the gall-bladder and bile-ducts.
9. How many bones in the human skeleton? Classify them.
10. Describe the blastoderm.

PHYSIOLOGY AND HISTOLOGY.

1. Describe the principal phenomenon that occurs when a muscle is physiologically active.
2. State with what principal functions pulmonary endothelium is endowed, and describe the origin and character of the blood which an alveolus utilizes during the physiological action.
3. Give the source and state the character of the blood supplying hepatic parenchymatous cells, and describe the two principal functions they possess.
4. State the effects of battery currents on the normal human nerves.
5. Give the process of regeneration of uterine mucous membrane following pregnancy.
6. Describe the physiological aspect of atavism.
7. Account for the contraction and dilatation of the pupil.
8. Name the circumstances influencing secretion.
9. What are structural elements? What is a typical cell?
10. Give the elements of the nervous system; the connective tissue.

CHEMISTRY.

1. Give tests for urea and uric acid, give chemical differentiation.
2. Test urine for albumin, sugar, indican, and phosphates.
3. Name antidote for phenol and treat case of poisoning.
4. Make tests differentiating the alkaloids, morphine sulphate and quinine sulphate.
5. Define medical jurisprudence.
6. Give symptoms of lead poisoning and treatment.
7. What are ptomains, and in what found? Give symptoms and treatment of ptomain poisoning.
8. What is hard water? How does it become hard? Give two ways of softening it.
9. What are the antidotes of bichloride of mercury? Give treatment for poisoning therefrom.
10. What is H_2O, H_2O_2, NaCl, H_2SO_4?

MATERIA MEDICA AND THERAPEUTICS.

1. Give origin and uses of carbolic acid.
2. Cinchona: Where found, chief alkaloids, uses, and dose.
3. Apomorphine: How obtained, use, dose.
4. Abstracts, extracts, infusions, tinctures, mixtures: define each.
5. What are hypnotics? Name three most important ones, doses, and indications.
6. What is the temperature of tepid bath, warm bath, and hot bath; indications for each.
7. Emmenagogues: When and how to be used; name three, with doses.
8. Name five mineral astringents; give dose of each.
9. Sweet spirit of niter, Hoffmann's anodyne: indications and dose of each.
10. Prepare and administer a purgative high rectal enema.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. Dysentery: Etiology, complications and sequelæ, and treatment.
2. Rheumatism: Give the different forms; treat each.
3. Tonsillitis: Differentiate from diphtheria; symptoms and treatment.
4. Give etiology and treatment of hemoptysis.
5. Intussusception: Define, diagnose, and treat.
6. Cirrhosis: Etiology, symptoms, and treatment.
7. Ascites: General causes, symptoms, and treatment.
8. Intestinal catarrh of children: Symptoms and treatment.
9. Describe the lumbricoides and give origin, symptoms, and treatment.
10. What diseases does meningitis complicate in children?

OBSTETRICS AND GYNECOLOGY.

1. Differentiate pregnancy from three possible ailments that simulate it.
2. What occasions vomiting of pregnancy? When is it pernicious, and what is remedy?
3. What preliminary knowledge of the patient should the accoucheur have?
4. Describe the possible hemorrhages of pregnancy and your method of checking them.
5. How long would you work with the newborn to bring about respiration, and with what methods?
6. Fully describe the third stage of labor, giving methods and dangers of delay in delivery.
7. Milk leg: Why so called, cause, and treatment?
8. When is curettage indicated? Give your way of doing it.
9. Give nosology, symptoms, and treatment of menorrhagia.
10. Nosology, symptoms, and treatment of vaginismus.

SURGERY.

1. What is suppuration? Give causes and symptoms.
2. Describe Syme's operation for amputation at the ankle.
3. Give the indications for reopening wounds.
4. Give the differential diagnosis of hydrothorax and empyema.
5. Give in detail the treatment of a compound fracture of the tibia.
6. What are the clinical symptoms and what is the surgical treatment of a purulent effusion into the knee joint?
7. Name the different kinds of fractures, and give differential diagnosis between fracture of neck of femur and dislocation of the hip joint.
8. Give in detail treatment of a punctured wound involving the deep palmar arch.
2. Give causes, symptoms, and treatment of osteomyelitis.
10. Give causes, symptoms, and treatment of phlebitis.

SPECIAL PRACTICE.

1. Give diagnosis of ulcer of stomach.
2. What is amebic dysentery?
3. Describe and treat adenoids.
4. What would you suspect from continued hoarseness?
5. Describe enucleation.
6. Define, describe, and treat cataract.
7. Diagnose impacted cerumen and treat.
8. Test the hearing. What is the most common cause of deafness?
9. Describe locomotor ataxia.
10. Describe paresis.

BACTERIOLOGY AND HYGIENE.

1. What is the difference between parasites and saprophytes?
2. What is the bacterium concerned in septicemia? How does it enter the body?
3. Describe the bacteria found in pneumonia. How are they transmitted?
4. Give a minute description of disinfecting the hands and instruments before performing an operation.
5. What group of bacteria are most resisting to disinfectants? Why?
6. What hygienic principles should be applied to our public schools?
7. Can tuberculosis be prevented? If so, how?
8. How would you prevent the spread of diphtheria and scarlet fever?
9. Give sanitary treatment of the puerperal state.
10. Disinfect a house after the recovery of a case of diphtheria. Give details.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

April 13, 1909.

ANATOMY AND EMBRYOLOGY.

1. The *general characters of a vertebra* are: Body or Centrum; and Neural arch. The latter consists of two pedicles, two laminæ, and seven processes (four articular, two transverse, and one spinous).
3. The *hip-joint* is an enarthrodial joint, formed by the

head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the ligamentum teres. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The ileo-femoral or Y ligament, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ileum, and below to the anterior intertrochanteric line. (3) The ligamentum teres. (4) The cotyloid ligament, which deepens the acetabulum, and bridges over the cotyloid notch, being there called (5) the transverse ligament. The joint has a very extensive synovial membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction, and rotation.

4. *Names of the regions of the abdomen:* Right hypochondriac, epigastric, left hypochondriac, right lumbar, umbilical, left lumbar, right iliac, hypogastric, and left iliac.

The *contents of any two* will vary, according to the position of the lines drawn. If the vertical lines are drawn upwards through the middle of Poupart's ligament, the superior horizontal line at the lowest part of the tenth costal cartilages, and the lower horizontal line at the level of the anterior superior spines of the ilium:—Then the *Right iliac region* will contain part of the ileum, part of the cecum, and the vermiform appendix; and the *Left lumbar region* will contain part of the left kidney; part of the descending colon, sigmoid flexure, and jejunum.

5. *The brachial artery* is the continuation of the axillary, begins at the lower margin of the insertion of the Teres major, passes down the anterior aspect of the arm, and terminates about half an inch below the bend of the elbow, where it bifurcates into the radial and ulnar arteries. It passes along the inner borders of the Coracobrachialis and Biceps muscles, it is superficial throughout its course, is accompanied by venæ comites, and at about its center is crossed by the median nerve, which passes from the outer to the inner side of the artery.

Branches: Superior profunda, inferior profunda, nutrient, anastomotica magna, and muscular.

6. The *inguinal canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries* are: *In front*: the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind:* the conjoined tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above:* the fibres of the internal oblique and transversalis. *Below:* Poupart's ligament and the transversalis fascia.

Contents: the spermatic cord in the male; and the round ligament in the female.

Differences between arteries and veins:—

ARTERIES.	VEINS.
Generally carry arterial blood.	Generally carry venous blood.
Carry blood from the heart.	Carry blood to the heart.
Do not collapse when cut.	Collapse when severed.
Are found contracted and empty after death.	Are not found empty after death.
The middle coat is the thickest.	The external coat is the thickest.
Do not have valves.	The medium-sized veins have valves.

7. *Triceps muscle*: The long, or middle, head arises from a depression on the axilliary border of the scapula immediately below the glenoid cavity; the external head from the root of the great tuberosity on the posterior surface of the humerus, and the upper part of the musculospiral groove; the internal head from the posterior surface of shaft of humerus, below musculospiral groove, and the internal and external muscular septa. It is inserted into the back part of the upper surface of the oleeranon process of the ulna.

8. THE GALL-BLADDER AND BILE-DUCTS. The *gall-bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage.

The *hepatic duct*, formed by union of ducts from right and left lobes, issues from the liver at the bottom of the transverse fissure. It passes downwards and to the right in the layers of gastrohepatic omentum, having the vena porta behind, and the hepatic artery on the left. It joins the cystic duct, the two forming the common bile-duct.

The *cystic duct* passes from the neck of the gall-bladder downwards, backwards and to the left, to join the preceding.

The *ductus communis choledochus* or *common bile-duct* is the result of the union of the hepatic and cystic ducts. It passes behind the first part of the duodenum, in front of the venæ portæ, with the hepatic artery on the left, between the layers of the gastrohepatic omentum, and, passing between the pancreas and second part of the duodenum, enters the small intestine obliquely, a little below the middle of the descending part of the duodenum by an opening common to it and the pancreatic duct.—(From *Aids to Anatomy.*)

9. There are 206 named bones in the human skeleton.

They are *classified as*: Long, short, flat, and irregular bones.

PHYSIOLOGY.

1. When a muscle is physiologically active, the principal phenomenon is contraction.

During contraction the following changes take place in a muscle: (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature (10) the electrical reaction becomes relatively negative, and (11) a sound is produced.

2. *The principal functions with which pulmonary endothelium is endowed* are: (1) To allow of the passage of oxygen into the blood, and carbon dioxide from the blood; thus acting physically as a permeable membrane. (2) To exert a selective influence on these gases; a vital process.

The *blood* comes from two sources: (1) From the branches of the *pulmonary artery;* this is venous blood for the lungs to aërate. (2) From the *bronchial arteries;* this is arterial blood to nourish the organ.

3. The *blood to the hepatic parenchymatous cells* is from two sources: (1) From the *portal vein;* this blood has circulated through the walls of the stomach, intestines, pancreas, and spleen; and is loaded with materials absorbed from the digestive tract. (2) From the *hepatic artery;* this is to nourish the organ.

The *two principal functions* are: (1) The secretion of bile; and (2) the formation of glycogen.

4. *The effects of battery currents on normal human nerves:* (1) A nerve impulse is developed at the moment the circuit is made; (2) a similar nerve impulse is developed at the moment the circuit is broken; (3) electric currents are developed on either side of the anode and cathode; (4) electrotonic alterations of nerve conductivity and excitability are observed.

6. "*Atavism* (Lat. *atavus*, ancestor) in the strict sense is a return to the peculiarity of the ancestral form of the species. As this ancestral form is generally unknown, the explanation of an unusual variation as due to atavism is in most cases merely conjectural. For example, the dark stripes that appear sometimes upon the back, shoulders, and legs of horses have been attributed to atavism by Darwin, Ewart, and others: the presence of these stripes being regarded as evidence of a striped ancestry when considered in connection with the coloring of other species of the genus *Equus*, like the zebra, quagga, etc. Another example of atavism is the occasional appearance of supernumerary mammæ and teats in women and in men. In women they have been observed to produce milk. These are regarded as atavistic because in the Lemuroidea, the lowest group of Primates, there are, in addition to the well-developed functional mammæ on the pectoral region, rudimentary teats upon the abdomen and groin. They thus approach the condition found in dogs and pigs, while in the apes and man there is normally but a single pair of mammæ."—(*Reference Handbook of the Medical Sciences.*)

7. *Contraction:* "The contraction of the pupil is caused by the action of the sphincter pupillæ. (1) If *light* falls upon the retina, the pupil contracts by reflex action. The course of the impulse starting in the retina and ending in the contraction of the sphincter is as follows: From the retina it travels through the optic nerve and optic tract to the anterior corpus quadrigeminum (probably). From there the pupil-fibers pass by Meynert's fibers to the center

of the sphincter pupillæ in the third nerve nucleus. Here the reflex is started, which passes out to the eye by the third nerve and its ciliary fibers. The contraction to light of the pupil of the eye illuminated is called the *direct action,* but the other pupil also contracts at the same time. This is called the *consensual action.* It is explained by the fact that the pupillary fibers of the optic nerve probably suffer semidecussation at the chiasm as well as the visual fibers. There is also a communication between the two corpora quadrigemina and between the third nerve nuclei. (2) The pupil contracts not only to light, but also to *convergence* and *accommodation.* It seems probable that the three centers for convergence, accommodation, and pupil-contraction, though independent, are stimulated simultaneously by the voluntary impulse for adjustment of the eyes for the near point.

Dilatation: "The presence of a dilator muscle is still in doubt. The elasticity of the posterior membrane and vasomotor action are probably in part active in dilatation. Dilatation is under the control of the sympathetic system. The center is in the medulla and the course is down the spinal cord to the seventh and eighth cervical and first dorsal roots, through the cervical sympathetic, carotid, and cavernous plexus to the eye. Physiologic dilatation is produced by irritation of sensory nerves and by psychic conditions such as fright or anger."—(From Alling & Griffin's *Epitome.*)

8. *The circumstances influencing secretion* are: (1) Blood pressure; (2) nervous influence; (3) "vital force" of the epithelial cells; (4) formerly, the physical processes of filtration, osmosis, and diffusion were supposed to be responsible for secretion.

9. *Structural elements* are the ultimate structures into which the tissues of the body may be resolved by the aid of the microscope. They are: (1) Epithelial; (2) connective (including bone, cartilage, blood, and lymph); (3) muscular; and (4) nerve cells (and fibers).

A typical cell is the ultimate element of structure; it enters into the formation of all tissues. It consists of a tiny mass of protoplasm, and contains a nucleus and an attraction sphere, but as a rule no cell wall. Cells vary in shape and size (from about 1-3000 to 1-300 of an inch in diameter); and are characterized by power of movement, assimilation, growth, excretion, and reproduction.

CHEMISTRY.

1. *Test for urea:* Evaporate a few drops of the urine (or other fluid supposed to contain urea) on a glass slide, moisten the residue with nitric acid, allow it to crystallize; crystals of urea nitrate will be recognized under the microscope.

Test for uric acid:—Moisten with nitric acid, and evaporate nearly to dryness; then cool, and add ammonium hydroxide. If uric acid is present the nitric acid residue is yellow or red, and a brilliant red is produced by the addition of the ammonium hydroxide.

Urea has the formula $CO(NH_2)_2$; it "crystallizes in transparent needles or four-sided prisms, without Aq; permanent in air; odorless, having a cooling, slightly bitter taste, resembling that of saltpeter. Soluble in an equal weight of cold water, very soluble in boiling water and in five parts of cold or one part of hot alcohol, the solutions being neutral in reaction. At 248° F. it melts, and slightly above that temperature is decomposed. It is found in the blood, chyle, lymph, humors of the eye, saliva, perspiration, bile, milk, serous fluids, amniotic and allantoic fluids, and especially in the urine."

Uric acid has the formula $C_5H_4N_4O_3$; it "crystallizes in small, colorless, rhombic, rectangular, or hexagonal plates, or in rectangular prisms. As crystallized from the urine, it is more or less colored by the urinary pigments, and the angles of the crystals are rounded to produce lozenge shapes, which are arranged in bundles, crosses, or daggers.

"It is odorless, tasteless, very sparingly soluble in H_2O, insoluble in alcohol and ether, soluble without decomposition in H_2SO_4 or HCl. Moist uric acid has an acid reaction. It is a dibasic acid."—(Witthaus' *Essentials of Chemistry.*)

2. To examine for *albumin:* "The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

To examine for sugar: First remove any albumin that may be present, then "render the liquid strongly alkaline by addition of sodium carbonate. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."

To examine for indicanuria: "The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filter is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess."

To examine for phosphates: Place one inch of urine in a test-tube; add half as much nitric acid; add a few drops of ammonium molybdate, and boil. In the presence of phosphates there is a yellow crystalline precipitate.

3. The *antidote to phenol* is said to be alcohol, or solution of sodium sulphate. *Treatment* consists in administration of albumin, saccharated lime, sodium sulphate, or strong alcohol, followed by lavage.

4. *Morphine sulphate* is soluble in about 15 parts of water, 465 of alcohol, and is insoluble in ether and chloroform.

If to a neutral solution of *morphine sulphate* a solution of neutral ferric chloride is added, a blue color will be produced.

Quinine sulphate is soluble in about 720 parts of water, 85 of alcohol, and 400 of chloroform.

If to a solution of *quinine sulphate* some chlorine water and then solution of ammonia be added, a green color will be produced.

5. Medical jurisprudence is the application of the knowledge of any of the branches of medicine to the problems and requirements of the law.

6. *The symptoms of poisoning by lead* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions and tetanic spasms."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic or by the use of the stomach tube."—(Witthaus' *Essentials of Chemistry.*)

7. *Ptomains* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction. They are found in proteid foods which have partly undergone decomposition.

Ptomain poisoning. Symptoms: Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and occasionally cutaneous eruptions. The prognosis is guardedly favorable.

Treatment consists in the use of emetics and cathartics, or lavage and rectal irrigation. Morphine may be indicated for the relief of pain, and collapse is to be combated by atropine, strychnine, nitroglycerin, external heat, whiskey, etc. After thorough purging, salol, naphthol, or bismuth may be given.

8. *Hard water* is water which contains an excess of calcareous salts; *temporary* hardness is due to the bicarbonates of magnesium and calcium; *permanent* hardness, to the sulphates of magnesium and calcium. Hard water can be softened by boiling, if the hardness is temporary only; permanently hard water can be softened by the addition of a little sodium carbonate.

9. The *antidote* for bichloride of mercury is: White of egg.

Treatment for poisoning by bichloride of mercury: Give white of egg in moderate quantity only, and follow with an emetic.

10. H_2O is the formula for one molecule of hydrogen monoxide (water).

H_2O_2 is the formula for one molecule of hydrogen dioxide.

NaCl is the formula for one molecule of sodium chloride.

H_2SO_4 is the formula for one molecule of sulphuric acid.

MATERIA MEDICA AND THERAPEUTICS.

1. CARBOLIC ACID. *Origin:* From coal tar oil, by fractional distillation; or, it can be made synthetically.

Uses: "As a disinfectant for surgical instruments, soiled linen, hospital apparatus, drains, privies, etc.; as an application for burns, carbuncle, endocervicitis, lupus, condylomata, and various other conditions, as an injection for leucorrhea and gonorrhea in the female; as a local anesthetic. Its antipruritic and parasiticidal qualities render it useful in many cutaneous affections; and it is employed locally in hay fever, influenza, and nasal catarrh. In the treatment of wounds it has been largely superseded by more powerful germicides. Internally: gastrointestinal irritation; malarial fever, typhoid fever, scarlet fever, and other zymotic diseases; influenza; by hypodermic injection in tetanus and bubonic plague."—(Wilcox, *Materia Medica.*)

2. CINCHONA. *Where found:* South America, on eastern slope of the Andes; also cultivated in India, Java, and elsewhere.

Chief alkaloids: Quinine, quinidine, cinchonine, and cinchonidine.

Uses: In malaria, and as a prophylactic against malaria; in neuralgias; in hay fever; in acute coryza; as a stomachic tonic; in influenza. *Dose:* Fifteen grains.

3. APOMORPHINE. *How obtained:* By heating morphine in sealed tubes with an excess of hydrochloric acid, when the morphine loses one molecule of water. *Use:* As an emetic; small doses are expectorant. *Dose:* As an emetic, gr. 1/10 of apomorphine hydrochloride, usually given subcutaneously.

4. *Abstracts* are solid, dry, powdered extracts of twice the strength of the crude drug.

Extracts are solid or semisolid preparations made by evaporating solutions of vegetable substances.

Infusions are liquid preparations made by heating a vegetable substance with hot or cold water; it is not boiled, though boiling water may be used.

Tinctures are alcoholic solutions of nonvolatile substances.

Mixtures are liquid preparations, containing one or more insoluble substances in suspension.

5. *Hypnotics* are agents which produce sleep somewhat resembling natural sleep.

Three important hypnotics: (1) Chloral hydrate; dose, gr. xv to xx. (2) Sulphonal; dose, gr. xv to xxv. (3) Trional; dose, gr. xv to xxv.

Indications: They are all used to produce sleep (when no pain is present).

6.

BATH	TEMPERATURE	INDICATIONS
Tepid.	About 85° to 95° F.	Personal cleanliness, to soothe the nerves, to allay the restlessness of fever, to lower the body temperature, to alleviate fatigue, both muscular and mental, and to relieve inflammatory conditions.
Warm.	About 95° to 100° F.	Much the same as above, but also to promote sleep and to relieve internal congestion and spasm; to dilate local bloodvessels, to stimulate secretions and evaporation; also as a diaphoretic in fever or uremia, and an anodyne.
Hot.	About 100° to 106° F.	The same as for *Warm*, but more powerful; also in renal diseases, uremia, and beginning colds.

7. *Emmenagogues* are agents used to stimulate the nonpregnant uterus or to restore the menstrual function.

Three emmenagogues: (1) Tincture of cantharides; dose, ♏j. (2) Oil of savin; dose, ♏j. (3) Oil of tansy; dose, ♏ij.

Indications: Amenorrhea, not due to pregnancy.

8. *Five mineral astringents, with dose:* Solutions of silver nitrate, lead acetate, zinc sulphate, alum, and ferric salts. Being used as astringents they are applied locally; hence, there is no dosage.

SURGERY.

1. *Suppuration* is a special form of inflammation, in which the exudate is unusually prolific in cells, and in which pus is found.

The *cause* of suppuration is the invasion of the tissues by pus-producing bacteria, when the said tissues are in a state of lowered vitality or are not capable of withstanding and disposing of the bacteria and their products.

Symptoms: Shivering or rigor, rise of body temperature, increase of leucocytes, the ordinary symptoms and signs of inflammation, throbbing pain, and sometimes fluctuation.

7. Fractures are variously classified:

I. Simple, compound, and complicated.

II. Complete (transverse, oblique, spiral, longitudinal), and incomplete (fissured, greenstick).

III. Single, and multiple.

IV. Comminuted, impacted, etc.

V. Intra- and extraarticular; intra- and extracapsular.

In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture.

9. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound or by extension from neighboring tissues, or they may be brought by the blood.

Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia, may be present.

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubercular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyelitis*, the *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

SPECIAL PRACTICE.

2. *Amebic dysentery* is dysentery caused by the *Ameba dysenteriae or Ameba coli*, an ameboid body, three or four times as large as a red blood corpuscle, granular in the center and clear at the margin, nucleated, and containing vacuoles, sometimes also containing pigment, bacteria, or other foreign matter. Abscess of the liver is often associated with this condition.

3. *Adenoids* are hypertrophied adenoid tissue in the nasopharynx.

Causes: The real cause is unknown, but the condition is generally observed in childhood; heredity is also supposed to be a factor; males are more frequently affected than females; malnutrition and scrofula seem to be causative factors; the condition is often associated with enlarged tonsils, enlarged cervical glands, hypertrophy of the nasal mucous membrane, deviations of the septum, spurs; it often follows some of the acute infectious diseases.

Symptoms: Mouth-breathing; snoring; open mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters.

Effects: Earache and other ear affections; mental deficiency; frequent attacks of coryza; nosebleed; stunted growth; convulsions, laryngismus stridulus, and various other neuroses may also be noticed.

Treatment: Complete removal, by curette.

4. *Continued hoarseness* might indicate: Laryngeal ulceration or exudation (simple, or tuberculous, or diphtheritic, or syphilitic); tumors; or disease or pressure upon the recurrent laryngeal nerve.

5. *Enucleation of the eyeball* is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the con-

junctiva, we may begin with a tenotomy of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day."—(May, *Diseases of the Eye.*)

9. Locomotor Ataxia. *Etiology:* It is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

Symptoms: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

Pathology: Tabes dorsalis is a condition in which the posterior columns and nerve roots of the spinal cord are degenerated, and which is characterized by incoordination, loss of deep reflexes, and various disturbances of sensation and nutrition.

The posterior columns of the cord are gray and shrunken and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

BACTERIOLOGY AND HYGIENE.

1. A *Parasite* is an organism which lives upon or within another (living) organism.

A *Saprophyte* is an organism which lives upon dead organic matter.

2. The bacterium most often found in septicemia is the *Streptococcus pyogenes.* This is a micrococcus, of spherical shape, arranged in chains of thirty or forty cocci (in liquid media), but fewer in solid media. Each coccus is about one-half to two microns in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

7. Tuberculosis is largely preventable. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk."—(Parkes' *Practical Hygiene.*)

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 10, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	492	142
Diphtheria	215	27
Measles	718	31
Scarlet Fever	108	14
Smallpox	—	—
Varicella	39	—

SCLEROMA OF THE UPPER RESPIRATORY TRACT.*

WITH A REPORT OF TWO CASES: RHINOPHARYNGO-LARYNGO-, AND RHINOPHARYNGOSCLEROMA. (VACCINE TREATMENT.)

By J. H. GÜNTZER, B.SC., M.D.,

NEW YORK.

ASSISTANT SURGEON MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

WHILE reports of scleroma cases and articles under the various headings of etiology, pathology, treatment, etc., are scattered throughout the medical literature in many languages, in English there is no account covering the subject *in extenso* and for this reason the writer has endeavored to correlate all the collected facts regarding scleroma of the upper respiratory tract which came to his notice during an extended search bearing upon this title.

At first met with in the clinics of the dermatologist, now the majority of cases are seen by the rhinologist, owing to the distressing symptoms mostly referable to the nose and pharynx, less frequently to the larynx. In 1870, Hebra[1] described rhinoscleroma, a tumor form (geschwulst form), as observed by him in nine cases (four males and five females), which he thought from the beginning to be syphilis but upon whom antisyphilitic treatment had no effect. Kaposi[2] in the same year gave the first histological description, finding a small round-celled infiltration of the corium and papillæ and likened it nearest to a glio or granulation sarcoma (Billroth, Virchow). Hebra remembers having seen a case in Paris in 1852 and thinks it likely to have been this disease. Weinlecher in discussing this paper remarked that in 1860 he had observed this disease in seven cases in Vienna in the clinic of Prof. Schu and thought them to be either syphilis or carcinoma. At this time nothing was known of the etiogenesis of this disease, Gerber,[3] however, in 1872, asserting it was due to some chronic inflammatory irritation, a view which has since been substantiated.

Scleroma has neither a geographical boundary, nor an ethnical limit. Cases have been reported from most European countries, from Egypt, India, Australia, Japan, Hawaii, South, Central, and North America. Endemic in Russia, Austria, Eastern Prussia, and Central America, in all other countries the cases are met with in the foreign born, although Kornfeld[4] reports two cases from Egypt in natives who had never left the country. Sporadic cases are very rare in the scleroma-free countries. This disease respects no climate, thriving as well in the rigorous north as in the tropical south. Among the sexes it is about equally divided. Up to 1903, about six hundred and fifty cases have been reported, the endemic regions in Russia, Austria, and Eastern Prussia furnishing the greatest number.

Scleroma of the upper respiratory tract may be defined as a chronic infectious granuloma pursuing a slow, progressive course and characterized by a nodular, compact infiltration of the nasal vestibule which steadily increases, growing outward and inward to complete closure of both nostrils and marked narrowing of the choanæ; this nodular infiltration later on changes the surface contour of the nose, and may invade the pharynx, larynx, trachea and bronchi, bringing about changes which will be discussed under the respective headings.

Location and Extension.—Always regional and of a distinct type, it may extend from the nasal mucous membrane to the lips and the cheeks, to the gums, antrum of Highmore, lacrymal ducts, eustachian tubes, nasopharynx, soft and hard palate, tonsils, pharynx, larynx, trachea, and even to the bronchi of the second and third order. In the nose the inferior meatus in both the turbinal and septal regions is most affected. The sense of smell being preserved in all cases, the upper part of the middle meatus as well as the superior meatus (olfactory distribution) are very likely not affected at all or else to a minimum degree only. It is found in the nasal vestibule, the ala, floor of the nose and on the lips. In the nasopharynx the most affected region is the plicæ salpingo-palatine, then the tubal promontory, the plicæ salpingo-pharyngeales, posterior surface of the soft palate and its free border, the uvula and the boundary of the posterior alveolar arches. The pharynx is oftenest affected at the posterior alveolar arches, the free borders, post pharyngeal wall, tonsils, and pillars. In the larynx the disease is found mostly in the subglottic space, then in the region of the petiolus epiglottidis on the posterior surface, the anterior wall is seldom affected. The rarest location is the mucous membrane of the mouth. Out of Baurowicz's[5] one hundred cases, only one had the tongue diseased, and only once did he see the hard palate alone affected. The outer nose was implicated in only thirteen cases. Zeissl[6] states that "the scleroma process occurs not only about the skin of the face or body, but may appear primarily in the laryngeal mucous membrane, trachea, or bronchi, and cause stenosis without any external appearance." One case was found where the scleroma showed on the skin of the arm and on the pharynx. He cites the following: Elzina and Pawlow saw the scleroma extend through the fissure orbitalis into the orbital cavity and cause an exophthalmus; Pick found a scleromal tumor in the external auditory canal. The scleroma process can extend from the nose through the lacrymal canal to the lacrymal sac and conjunctiva. A very rare case was that of v. Schrötter with great contraction of the pharynx and ankylosis of the jaw bones.

*Read in part and cases presented before the New York Academy of Medicine, Section on Laryngology and Rhinology, March 24, 1909.

Mikulicz[7] observed the disease extend around the mouth and almost obliterate the oral opening; he also points out the fact that "rhinoscleroma does not affect bone by either caries or necrosis," although Koschier[8] found soft bone on the removal of scleromatous tissue from the nose with the nasal bones

Fig. 1.—Case I—Showing the nasal occlusion by the infiltrated mass and the nodular deformity of the nose, most marked across the bridge on the left side.

and part of the superior maxilla. It is also doubtful if the process includes the nasal cartilages. In one of Streit's[9] cases the septum was soft and easily broken through without much pressure.

Infection Atrium.—The precise point of origin of this disease, whether from the nasal wings, or the mucous membrane of the septum, floor of the nose, turbinates (anteriorly or posteriorly) the pharynx, larynx, trachea, or bronchi has never been positively demonstrated. Bojew[10] states that it does not necessarily begin in the nose; its origin may be from any part of the respiratory tract. While the disease is nearly always symmetrically divided, affecting both sides, it may seldom happen to be unilateral. Pawlowsky[11] reported three cases, where one nasal chamber alone was diseased in the form of a polypus, which in each case was diagnosed microscopically as rhinoscleroma. Another atypical case is mentioned by Zwillinger[12] in which the growth extended from the left vestibule to the lips, right nostril free, the uvula gone, and the pharynx affected, with a histological diagnosis of rhinoscleroma. Freudenthal[13] reported a similar case with involvement of one side of the nose and lips only, each growth being isolated from the other, although in this case the pharynx and larynx were also implicated. Another case of unilateral rhinoscleroma was treated by Schein.[14]

Whereas primary laryngeal cases are generally admitted to be very rare, Paltauf[15] out of fifteen cases found the disease limited seven times to the larynx and trachea, a rather high percentage when compared to the eighty-seven cases of Wolkowitsch[16] with five limited to the larynx and Juffinger's thirty-eight cases with also five limited to the larynx as quoted by Streit.[9] Baurowicz, among his one hundred cases had only six of primary laryngeal and two cases of primary bronchial scleroma; according to this author Catti, Pieniazek, Lumin, and Kobler have seen primary laryngeal scleroma, the case of Kobler never extending any further than the larynx, and extension to the bronchi has been found upon necropsy by Straganow in two instances and in one instance by v. Schrötter. Baurowicz thinks the infection atrium is on the floor of the nasal chamber and from here the disease extends backward and forward. Lustgarten[17] also reports a case of primary laryngeal scleroma. E. Mayer[18] presented the history of a case of laryngeal scleroma in 1907 and a further report of the same case in February of this year in the same journal. Rydygier, Jr.,[19] also had a case of laryngeal scleroma.

Age of Onset.—Its slow and insidious growth, its chronicity, and its unknown focus of origin, make it extremely difficult to say at what age the scleroma process begins. Gottheil[20] in a recent article asserts "he knows of no case in childhood. All cases occur in the third decennium or later." This view may have been tenable some years ago when only adult cases presented themselves to the dermatologist for their cutaneous lesion and the external nasal deformity, phases of the disease which manifest themselves at a late stage. Yet in more recent years so many cases occur during adolescence which come to the rhinologist with the disease in the same well-advanced stage, that, considering its slow, progressive growth and its usual extension from within outward, the contention is strong that scleroma may begin in childhood, at least some years before these adolescence cases come under observation.

A goodly number of the cases reported occurred in young adults under twenty-one years of age, in whom presumably the disease was in progress long before any of the symptoms which attracted their attention displayed themselves and prompted measures for relief. Streit[9] found the disease at the age of fourteen and twenty, respectively; one of my

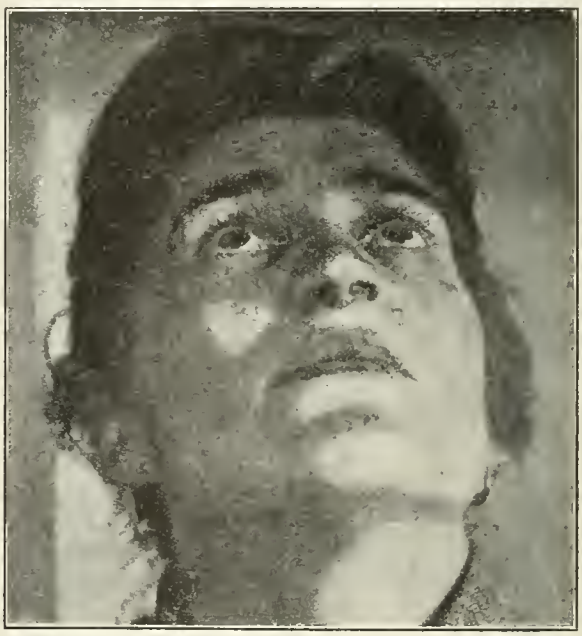

Fig. 2.—Case II—Showing the nodular deformity of the nose; the nasal occlusion by the infiltrated mass, and the cutaneous lesion on the right upper lip extending downward from the right nasal wing and vestibule.

cases came under observation when nineteen years old and he claims to have had the disease since his seventh year. Dr. W. Freudenthal, of this city, who has had experience in this class of cases and to whom reference has been made above, informed me about a year ago that he then had under treat-

ment a rhinoscleromatous child nine years old. Wolkwitsch in his tabulated cases mentions No. 49, boy twelve years old, native of Central America, who had the disease more than eleven years. Rydygier, Jr., out of fourteen cases, had thirteen range in age from seven to twenty years, all girls. Baurowicz reports a girl eleven years old who had been suffering for one year and an eighteen-year-old boy who had the disease for an indefinite time since childhood. O. Mayer[21] claims most cases are afflicted between the ages of fifteen and twenty-five. It may be admitted that the majority of cases probably occur in adults, yet of the reported cases enough are afflicted early in adolescence to augment my contention that some of these cases do occur in childhood and for which the cases herewith abstracted seem ample proof.

In agreement with some of the foreign authors who contend that the prevalence of this disease is underestimated it may be added, that when it is more generally recognized, its rarity will give place to frequency, and then, too, the minimum age of onset will be greatly reduced.

Etiology.—Scleroma has no racial predilection, its occurrence rather depending upon the cultural, economic, or material condition of the people. With only two or three exceptions in the literature it is a disease confined to the poorer classes. Streit[22] maintains the disease was brought over the border into Eastern Prussia from Russia, by the poor people going back and forth to buy cheaper meat. Lax hygienic surroundings are the chief predisposing factors. In the endemic rural districts, especially of Galicia and Russia, where the disease prevails among the farm laboring class, the reported conditions are miserable. In close contact with the live stock, it was at one time believed that man contracted the disease in this way. Lissauer[23] quotes "Dierkshoff, Pathologie u. Therapie für Thierärzte" that horses and swine have rhinoscleroma. He raises the question whether or not domestic animals have rhinoscleroma. Up till now, no animal cases have been found. Trauma likewise was in some instances thought to be a predisposing factor in the causation of this disease; cases were reported by Hrach,[24] Barth,[25] and Lang[26] in which rhinoscleroma developed shortly after a traumatism to the nose, none of the patients having had any catarrhal symptoms before. Barth's case was interesting, the patient developing the disease after a horse bite, but the horse was well and remained well. Wolkowitsch speaks of a case developing after the application of leeches to the nasal vestibule, and the disease was most marked at the point of attachment. These patients very likely had scleroma before the trauma.

It remained for Frisch[27], in 1882, to demonstrate a more definite factor for the etiology of this disease. He described a peculiar bacillus in the rhinoscleromatous tissue examining twelve cases, finding it in the cells, between them and in the interfibrillary spaces of the connective tissue.

Morphology of the Frisch Bacillus.—The Frisch bacillus is a short rounded rod about 0.8 u broad, the length slightly variable and was best seen in the tissue with the haematoxylin—eosin stain. In culture smear they show a large, regular, sharply defined, sparsely colored capsule as first described in 1885 by Cornil and Alvarez[28]. The bacillus is lengthwise homogeneous, often in pairs, or else is seen as a diplo-bacterium not unlike that of the Friedländer bacillus. But in the tissue it is distinguished particularly by its larger capsule and that often a few bacteria are found parallel or in an irregular form surrounded by one capsule. The capsule is compact and is less colored about the sides of the bacillus than at the periphery. Sometimes the capsule colors deeply and at times is wanting. The Frisch bacillus is easily grown on agar-agar, agar gelatine, and potato. Bouillon and pepton water are both made turbid by this bacillus. Gelatin stabs produced nail growths without liquifaction after some weeks. After 24 or 48 hours, on slant agar-agar, the culture can be seen as a broad, uneven, thin, whitish-opaque, shining and irregular layer. The water of condensation is clouded, viscid and has a whitish bottom precipitate. Old cultures show the capsule formation better. In still older cultures it was noticed that the bacilli become distinctly shorter and thinner. With glucose agar there is no gas formation. It does not coagulate milk.

The Frisch bacillus forms no spores. In culture smear it is Gram negative and in the tissue it varies according to the hardening fluid used, when hardened in alcohol it shows a Gram negative reaction

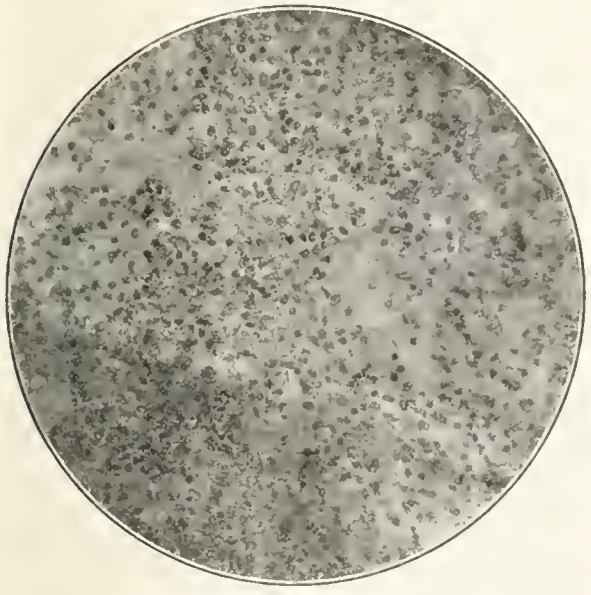

Fig. 3.—Photomicrograph with projection eyepiece No. IV. and DD objective; showing the so-called Frisch bacilli in the Rhinoscleroma tissue; in the vacuole (Mikulicz) cells and the tissue proper.

but hardened in Osmic acid, Müller or Zenker fluid it shows Gram positive. (Perkins[29].) The writer has also found the Frisch bacillus Gram positive in the tissue when hardened in a 5 per cent formalin solution. Many investigators claim that the Frisch, the ozena and Friedländer bacilli are only different forms of the one group. The Frisch bacilli were observed by me in the hanging drop and were noticed to possess a lively motility, lasting almost three days. An agglutination test, like that of Widal for typhoid, was also tried for the first time and the Frisch bacillus was found to have no clumping tendency. It would be further interesting to try this agglutination test, with other scleroma patients, whose immunity has not been influenced by bacillary or vaccine injections. The morphological and biological difference between the Frisch bacillus and the Friedländer bacillus will not be gone into here, reference can be made to the work of Kolle and Wassermann[30] which in part was followed in this bacteriological work.

de Simoni[31] questions whether or not these bacilli to which the eteogenesis of rhinoscleroma is

ascribed may not be accidental guests of the nasal mucous membrane. He claims that he found an identical capsule bacillus like that of Frisch in ozena and considers all like bacilli only a form of the Friedländer Pneumo-bacillus. With strict obedience to the rules of technique he found a Frisch-like bacillus 7 times in 58 individuals and in 18 animal tests once in the mucous membrane of a rabbit and once in a dog. All told, 9 times out of 76 examinations, in all morphologically and biologically the same bacilli and identical in their nutritive development. Perkins, in a study of the *Bacillus mucosus capsulatus* group to the rhinoscleroma bacillus, found bacilli of this group in an ordinary case of polypus somewhat inflamed, also in two cases of marked turbinate hypertrophy, and concluded "that the endemic quality of the disease, the apparent absence of transmission by contact in spite of the number of organisms in the nasal exudate and the sporadic type of the disease outside of its narrow endemic limits, are all against the rhinoscleroma bacillus as a causative factor, and its presence in the cells is due to secondary invasion or ingestion rather than to infection."

V. Babes, in Kolle and Wassermann's work, asserts "that there have been no conclusive grounds found upon which to assign for the Frisch bacillus a primitive rôle in the tumor formation. In fact, a mucous forming capsule bacillus is found in the majority of the cases of rhinoscleroma that coincides with many of the strains of the ozena, the Friedländer and the capsule bacilli of the nose and bronchi, and it must be remembered further that up to date there has been no positive differentiation made between the "rhinoscleroma bacillus" and certain other capsule bacilli found in the nose. Therefore there is at this time no strong scientific foundation, upon which to base a differentiation of the Frisch bacillus from the other capsule bacilli and to assert that it is the specific virus for rhinoscleroma.

Dittrich[32] considers the disease due to a mixed infection. Lissauer cites Klemperer and Scheier "that the rhinoscleroma bacillus and the ozena bacillus are identical with the Friedländer bacillus, and that they are largely increased in scleroma and ozena. Wolkowitsch does not believe the Frisch bacillus stands in any causative relation to the disease but does so stand to the cell degeneration.

Biological Experiments.—Various biological experiments with the Frisch bacillus have been tried by investigators upon the different laboratory animals with a few positive results, but usually they proved negative. Stepanow[33], by inoculating with a pure culture (2d generation) into the anterior chamber of the eye of a guinea pig, and in another by implanting a piece of tissue into the anterior chamber of the eye had positive results, finding on examination the pathological characteristics of the rhinoscleroma of man; he concludes that "the reason the experimental granuloma did not arise in the mucous membrane of the respiratory tract is, that with the origin of the scleroma a certain anatomical territory does not play the chief rôle, but that a peculiar microorganism decidedly does, for whose development just this territory is favorable and mayhap in the human organism (the respiratory tract) is alone the one to offer favorable conditions." Pawlowsky also claims success with inoculation. He injects a pure culture of rhinoscleroma bacilli together with warm agar-agar into the abdominal cavity of a few guinea pigs; after 24 to 48 hours the animals usually die. Out of the exudate of the peritoneal cavity one gets pure cultures of the rhinoscleroma bacillus with capsules; from the heart, liver, spleen, kidney, blood, and bone marrow pure cultures of the rhinoscleroma bacilli can be grown. He claims, too, that the intraperitoneal injections into guinea pigs of the ozena and Friedländer bacillus with agar-agar do not cause death, as the rhinoscleroma bacilli injection do, and that this test is a sure diagnostic method. Kraus[34] inoculated a white mouse subcutaneously with the rhinoscleroma bacilli and found the bacilli burrowed quite deeply in the tissue after 24 hours, and after three days could demonstrate the typical Mikulicz cells. With the Friedländer bacillus he had a similar experience, it, too, gave an analogous histological result, finding in the granulation tissue the Friedländer bacillus and the Mikulicz cells. In the liver, spleen, and kidneys, in both the Friedländer and rhinoscleroma mice upon autopsy, he also found the bacilli intra- and extracellular. v. Frisch, in his animal inoculation had no result even after eight months' observation. Rydygier mentioned in Lissauer's report, injected into monkeys without result. My own experiment with a monkey proved negative after five months' observation. de Simoni applied the bacilli to the nasal mucous membrane of a tubercular subject intact and traumatically with negative result. (Such a procedure is to be vehemently condemned at any time.) Lissauer also cites v. Schrötter, who put pieces of rhinoscleroma tissue under his own skin, which caused a phlegmon and swelling of the lymph glands, in the pus of which were found bacilli of the rhinoscleroma type, but there was no further infection. The time factor has probably been overlooked in a good many of these experiments and, as Marschalko[35] so aptly states, "after inoculation, a few weeks or a few months may not be long enough to cause rhinoscleroma, since it is a very chronic disease and the infection goes on a long while before it shows any symptoms." Although most attempts to propagate this disease by inoculation have been futile, and though dissenting from some of the opinions noted above, in view of the fact that the so-called Frisch bacillus is constantly found in certain parts of the scleroma tissue, and a pure culture of the bacillus is always obtainable from the tissue or the exudate, and since local immunity and improvement was obtained by me with a vaccine of the Frisch bacilli, it may be accepted that the Frisch bacillus plays an important rôle in the causation of scleroma.

Infection and Contagion.—From the time that Frisch demonstrated the bacillus which is always present in the tissue of scleroma, excepting the few dissenting voices already noted, it is admitted, by most writers on this subject, to be an infectious disease. In both of my cases 10 cc. of blood drawn from the median basillic vein and cultured in bouillon for 72 hours, showed sterile smears, hence the infection is probably only a local one and not systemic. Some admit its bacterial pathogenesis but class it with the symbiotic infections. Instances that bespeak the contagious nature of scleroma have been published by Streit[22]; reporting 18 cases with positive diagnosis, he found other members of the same family afflicted with the disease in four instances, respectively, as follows: two sisters, two brothers, two brothers, and two sisters, also two instances in which from the history it was shown that others in the family had very likely died from scleroma. In another communication[9] he mentions ten cases

within a radius of three square miles, in which three members were afflicted in one family, two in another and two cases lived in the same village. Baurowicz admits that, even if its degree of contagion is slight, still a number of cases are observed in the same place and where more than one member of the same family have been diseased; he saw two sisters, and at another time two brothers affected. In consequence of its situation in the upper respiratory tract he is led to believe that it is an "air borne" disease. O. Mayer, in his work, with reference to the question of contagion, says "in favor of contagion are the cases in the same place and those in the same family, citing where a mother and daughter were afflicted in one family and where the mother's sister and this sister's husband and their daughter were also afflicted. (This is the only phylogenetic history, if I may use the term, of possible contagion that came to my notice.) In another instance he mentions a husband and wife as subjects of scleroma. He makes the point that its contagiousness is probably mild, since patients have been utilized as nurses in some hospitals, with no enforced isolation, yet in this close relation, no case of contagion has come to notice. Fomites may play some rôle in its extension, and the writer believes that coughing, expectorating and sneezing may be disseminating agents and that an insect or parasite may be responsible for its transmission from one individual to another. Liuck[36] considers scleroma contagious and finds an added danger in the fact that these patients do not feel sick and so freely mingle with others. Intimate and prolonged association may have something to do with infection or contagion.

This disease being of doubtful progeny, its incubation period unknown, and its means of transmission still obscure, little can be said as to its positive contagion, however, from the gathered observation of the different authors, as noted above, and rhinoscleroma being generally accepted as an infectious disease, we may assume its possible contagiousness, mild if you please, until the mooted factors enumerated are decided. For social as well as scientific consideration, it has been recommended by various authors abroad to register scleroma under the communicable diseases and to isolate and even segregate these patients as is done with leprosy.

Though far away from the endemic centers, some time in the future, near or remote, perhaps the emigration or national health authorities in the United States may have to reckon with this disease, and, for cogent reasons, may possibly have to consider deportation or some other appropriate, if less harsh, but not less stringent regulation to limit this horrible and pitiable disease.

Histopathology.—Hebra, in his first microscopical examination of rhinoscleroma tissue, noticed that the cells in the new formation nowhere show the faint, finely granular and poorly defined contour and indistinct nucleated appearance (so-called disintegration) of the cells, as in syphilis and lupus. On the contrary, they were well preserved with sharp contour and clear nuclei with good imbibition. Kaposi found a small-celled, dense infiltration and compared to it the small-celled sarcoma (granulation sarcoma). Tanturri[37] coincides with Hebra, except as to the histological character of rhinoscleroma. He found the epithelium greatly prolonged and the whole tissue largely intersected by epithelial masses which contained numerous epithelial pearls and came to the conclusion that rhinoscleroma was an epithelioma or an adenoma. Mikulicz admits that in some places one will find large epithelial masses and if such a one is examined a false diagnosis of an epithelial new formation is made. He was convinced from his study that rhinoscleroma is an extraordinarily slow progressing inflammatory process, which begins in the tissue as a small cell infiltration that causes the gradual disappearance of the normal tissue elements and without leading to any disintegration of the infiltrated tissue is finally formed into a more or less dense, shrinking connective tissue, and while the process comes to an end at the place first invaded it strides onward at the periphery. He first described the hydropsical cells of rhinoscleroma tissue, which are now known as the Mikulicz cells, or "Schaum Zellen" (foam cells) as Unna calls them. Mikulicz describes these cells as follows: The adventia and its neighborhood is filled with small cells; their form and size vary, we find some round, others longer, from the size of a red blood corpuscle to that of a white corpuscle, in all degrees of size. All have a well-colored nucleus and a scarcity of the distinct granulated protoplasm; the farther away from the vessels however, the more they loose their regular form and now one sees cells, larger in the protoplasm and more irregular in form but otherwise the same; others change their character entirely but not all in the same way. We find two distinct changes; in the one they swell up, the protoplasm and their contour are less visible, the nucleus either disappears entirely or else is also swollen and hardly to be recognized, sometimes it is entirely wanting and then shows a vacuole. The size of the cell becomes so large that its diameter is three and four times the size of the smaller ones. The other group of cells grows, too, but not so excessively and not at the expense of their vitality; their nucleus is sharp and well colored, the protoplasm distinctly granular, and by longer or shorter prolongations extends in different directions; such prolongations from one to five in number to a cell, often reach far between other cells and can be seen united to the prolongations of other cells. They do not always grow in an indefinite direction or with irregular prolongations, but a time comes when they have the prolongations limited to two, one at either end, and form the spindle-shaped cells.

These Mikulicz cells are not pathognomonic for rhinoscleroma but are also found in lepra, glanders and bubonic plague as cited by Dittrich[38], and in the granulation tissue of wounds, malignant edema and other inflammatory edemas and in acute inflammation of the sweat glands, as reported by Mibelli[39]. Marschalko claims "the Mikulicz cells are degenerated connective tissue cells, the degeneration being due to the invasion of the rhinoscleroma bacteria, which are contained in the 5 or 6 gloea of the Mikulicz cell, whose body slowly enlarges, becomes bloated and the protoplasm assumes a reticulated appearance. The cell nucleus in the beginning is well preserved, later shrunken and degenerated, either in the middle of the cell or pressed to the cell wall." The epithelial layer of rhinoscleroma tissue is little changed or not at all. It has been observed to be thickened at times and infiltrated with leucocytes.

Another pathological entity of rhinoscleroma are said to be hyaline cells or globules, also known as "Russel bodies." Pellizzari,[40] in 1883, was the first to demonstrate hyaline degenerated cells in this disease. According to Unna[41] the hyaline globules in the plasma cells appear faceted and do not resemble

any organism; freed from the cell membrane they take the globular form or if they had the seldom-prism form, they take a cylindrical form and then resemble certain organisms, especially bacteria (encapsulated) as the rhinoscleroma bacilli. For this reason the hyaline globules and bacilli were often mistaken one for the other in the examination of rhinoscleroma tissue, since the hyaline globules and the capsule of the bacteria take the same stain in most cases. Hyaline degeneration of the connective tissue cells, as recorded by Kanstantinowitsch[42] is also found in tuberculosis, syphilis, lepra, chronic granulating processes, in epithelial (in the interstitial tissue) and mesodermal tumors, in the mucous membrane of the stomach, intestines, etc., in all malignant new formations, Marschalko having found them in carcinoma, sarcoma and in a case of ulcus ventriculi. So that according to Unna[43] one cannot attribute them as a characteristic of any particular one of these diseased processes, nevertheless a richness of hyaline cells is only found in rhinoscleroma, actinomycosis and Madurafuss, and therefore hyaline cells as well as the Mikulicz cells can be considered characteristic of rhinoscleroma; the Mikulicz (hydropsical) cells appear colonized in certain parts of the rhinoscleroma swelling and impart the soft feel, whereas the hyaline cells are more evenly distributed over the whole tissue, in the soft as well as the hard parts.

The hydropsical cells are a good culture media for the bacilli which to a certain extent invade the interior of these cells. The hyaline bodies or globules have no relation to the bacteria, although they may be a by-product of the invading parasite, yet they are never found in the hyaline cells. The hydropsical cells are derived from the spindle cells (Mikulicz held the reverse view) as well as from the plasma cells. The hyaline globules are derived from the plasma cells only.

Mibelli makes an interesting distinction for the Mikulicz cell and the hyaline cells of rhinoscleroma: "The characteristic cell for rhinoscleroma is the hydropsical cell of Mikulicz, which is a much larger cell than the ordinary 'foam cell,' it is irregular in outline, rather long, and contains in its interior a hollow cavity, sometimes two or more cavities, embracing a colony of bacilli. These cavities are decidedly larger than those of the ordinary foam cells. The refraction and reaction of these embedded bacillary colonies within these large endoprotoplasmic cell cavities show that they contain a half fluid homogeneous substance probably formed from the cell protoplasm. This seems probable when one considers that these bacilli on artificial media cause a clouded, viscid fluid much as one observes oozing from the nose of these patients. Hence the cell degeneration caused by the rhinoscleroma bacilli is an hydro-picmucin degeneration brought about by physicochemical changes due to these same bacilli. The hyaline cells found in rhinoscleroma seem to differ from the others, they have a vitreous appearance and always color red, whereas in the gentian, iod-eosin method, the ordinary or globiferous hyaline cells color violet. These vitreous hyaline cells are constantly found in rhinoscleroma but not in the other pathological processes. Mibelli finds the bacilli only in or near these Mikulicz foam cells.

We come now to the acknowledged instigator of the above-described cell degenerating in this tissue —the Frisch bacillus, whose bio-morphological character has already been pointed out. Frisch found his bacillus in the protoplasm of the large Mikulicz cells, between them and in the interfibrillary spaces of the connective tissue, using 1/20 Reichert's ol. immers., with the low power the bacilli appeared as cocci; he concludes that most likely through these bacilli the retrogressive metamorphosis of the cells, which manifests itself by the loss of the cell nuclei, gradual enlargement of the cells at the same time that the protoplasmic nuclei disappear and the final transformation of the cell protoplasm into a liquid substance takes place, and since this infiltrated connective tissue never comes to necrosis, this condition must be taken as a chronic inflammation. Wolkowitsch[44] is the only one who reports having seen the bacilli in the hyaline masses themselves, using the Gram stain. Marschalko agrees with Unna that the lymph vessels are primarily diseased and that the bacilli invade from these the intercellular spaces and the tissue cells. He noticed the bacilli in the Mikulicz cells embedded in the glœa of the protoplasm and in more recent diseased tissue in the lymph vessels; he never saw the bacilli in the blood vessels nor in the hyaline bodies; neither could Schridde[45] find any bacilli in the hyaline bodies. Streit in some specimens could trace the bacilli from the superficial layers of the mucosa to the interepithelial bacilli clumps, showing that the bacilli enter from without. Baurowicz also claims to have found bacilli in the epithelial cells. Various staining methods have been advocated, the different procedures can be learned by referring to the works of Unna, Frisch, Mibelli, Noyes[46], Streit and Marschalko.

We have then this triad of histopathological conditions that make up the microscopical picture of rhinoscleroma, viz., the bacilli, and these mostly in their generally accepted distinctive habitat—the Mikulicz cells—and the hyaline bodies. But the warning must be heeded and a large enough piece of the diseased tissue for a proper examination utilized, otherwise, as already pointed out, a false histological diagnosis will result.

Symptoms and Clinical Courses.—In most cases there are no changes in the contour of the nose externally, which would cause suspicion, except in the later stages. When these changes occur the nose may become greatly enlarged, especially broad over the bridge, or there may be nodal enlargements, flat or raised, over the lateral nasal cartilages, on top of the nose, at the ala, septum, and at the junction of the vestibule and lips. These nodes are sometimes sharply defined. The adjoining skin has a normal appearance but at times is reddened. Hard nodular excrescences are seen on the upper lip, at the junction of the nasal vestibule and ala, and of the septum and lips in color light or brown red, sometimes crossed by dilated vessels, smooth, shining, without hair and covered by a dry, cracked epidermis, which at times is bathed in moisture or else covered by crusts. These nodes and excrescences are painless, except on pressure. From the upper lip they may extend to the lower lip, encircling the mouth.

Premonitory symptoms are wanting unless the chronic catarrhal symptoms "rhinitis skleromatosa" of Streit can be considered as such. Usually repeated epistaxis is noticed, with later crusting and foul smelling nasal secretion. A mousey and garlic-like odor, which some claim as characteristic, and which is realized by the patients themselves since their smell sense is intact, was observed in these cases. Rarely cases with wide nasal chambers and the peculiar odor may resemble ozena as

cited by Streit. With the thickening of the interior soft parts of the nose, sometimes to entire occlusion, and with the advance of the disease to the eustachian tube, deafness and tinnitus may be complained of. Loss of taste or difficulty in protruding the tongue occurs when that organ is affected. Pain on swallowing is due to extension to the palate and fauces. Ankylosis of the jaw due to adhesions has been observed as well as almost an entire obliteration of the oral opening. Dryness of the mouth and pharynx, hoarseness, difficult nasal breathing, and nasal intonation of the voice are common. In consequence of the disease extending to the fauces and mouth, causing pain and contractions, the nutrition of the patient may suffer; usually they are robust and show no cachexia, at least during the early stages. Later loss of weight ensues. In the train of the disease as it advances, follow frontal headache and pains radiating to the ears, jaws, mouth, and throat.

In the nose and pharynx, the nodular infiltration appears at first, soft, dark red, circumscribed, and uneven; later it takes on a grayish-white color, becomes hard, diffuse and reaches deep into the submucous tissue, but so far as known does not affect the cartilages of the nose. Seldom it appears in a polypoid form (Baurowicz, Pawlowsky.) Still later it is covered by vessels and may lay in folds as shrinking goes on, becomes paler, and is transformed into scar-like tissue causing contractions and the pulling together of the soft parts in the pharynx and fauces. In the nose we may have synechia. The infiltration of the mucous membrane does not ulcerate, but the epithelium desquamates, and this gives it the appearance of ulceration, especially in the pharnyx and the soft and hard palate. When it affects the skin we have true ulceration, with discharge and crust formation. Entire occlusion of the anterior vestibular opening of the nose frequently occurs, but entire occlusion of the choane is probably never found. Baurowicz never met it in his 100 cases. Adhesions in the nasopharnyx are rare, but the soft palate may contract and be raised upward and backward, taking the uvula with it, and to such an extent as to make an examination of the nasopharnyx impossible. The thickening of the tonsils and pillars greatly narrow the fauces, and they have the same studded or mottled-red and white appearance as the surrounding tissues.

With the advent of the disease to the larynx, hoarseness, cough, expectoration, and dyspnea manifest themselves. The process here is subcordal, beginning anteriorly and gradually grows backward below the processus vocales; it may seldom grow in a reversed way. It appears in the form of a "chorditis vocalis inferioris hypertrophica," adherent to the surface of the cords, and, as seen above in the pharynx and nasopharynx, is at first red and later becomes paler, reaching the same shrinking stage, thus bringing the vocal cords closer together and so encroaches on the glottic opening. Sometimes the true and false cords become thickened as well as the aryepiglottic fold, the inner surface of the arytenoids and the epiglottis, thereby causing stenosis and disfiguring the anatomical landmarks. Any of these parts may be affected singly or collectively, this of course hampering the motility of the cords and arytenoids. An edematous infiltration may likewise be noticed. Choking spells occur. Extension to the trachea and bronchi have much to do with the irritable and metallic cough of some patients. Pulmonary symptoms are usually wanting, excepting where laryngeal and bronchial involvement takes place, when the physical signs and symptoms of air hunger are in evidence. The affection of the larynx in this disease has often been said to resemble "Störks blenorrhea," with which it has much in common, symptomatically. The laryngeal cartilages are probably never affected.

Metastasis.—Metastasis in rhinoscleroma is admitted by only a few of the many foreign writers and Wolkowitsch and Lang are emphatic in their statement that metastasis does not take place in rhinoscleroma. Róna[47] first mentioned metastasis as occurring in this disease. He records one of his own cases and cites four others. In his case the disease had progressed for 24 years. The glands below the chin and angle of the jaw, and of the neck were enlarged to the size of a large bean; the axillary and inguinal glands were also enlarged. From a section of the submaxillary glands he cultivated, on agar and bouillon, the pure rhinoscleroma bacillus. Blood from a vein in the arm gave no culture and from a cut in the cheek the culture was likewise negative. Glands showed hyaline degeneration.

de Simoni quotes Wilde (Inaug. Diss. Bonn. 1896), who found the Frisch bacillus in two individuals who had rhinoscleroma; in one in a varicose vein abscess, and in the other in an arm injury.

Diagnosis.—For the clinical diagnosis of rhinoscleroma, little would be gained by any addenda to the eight points for diagnosis as compiled by Gerber,[48] which are repeated here in full.

1. Changes of the nose externally which would cause suspicion are wanting in most cases.

2. The occlusion of the nose, which is often the beginning of the disease, shows on rhinoscopic examination to be due to the thick, rigid, at the beginning soft, later very hard, more or less nodular swellings of the mucous membrane of both the septum and turbinates, and which sooner or later fill up the entire nose.

3. These typical changes are not always found anteriorly but are seen first, with posterior rhinoscopy, as a narrowing of the choanae from thickening of the septum, the eustachian prominences and the lateral folds of the mucous membrane.

4. Often the pharynx is found normal on direct examination, but here, too, in some cases, we see scleromal infiltration, which reminds one of syphilis and tuberculosis, hypertrophies, contractions and tumefactions of the soft palate and the posterior pharyngeal wall.

5. Sooner or later, mostly in the very chronic course of the disease, the larynx becomes affected by stenosis, due to subglottic swelling; the swelling may be above the chink. In some cases the larynx is primarily affected and the disease extends upward.

6. The secretions may be normal, in other cases may show a picture of ozena and "ozena trachealis."

7. It is characteristic of these thickenings, excepting in the very beginning, that they are hard, tough and rigid, and do not ulcerate, although a superficial secondary erosion is seen now and then.

8. Finally the microscopical examination will show the Mikulicz cells and the bacilli of Frisch.

Gerber "thinks a good many of the scleroma patients have brothers and sisters die from the disease in their county districts, whose deaths are supposedly due to consumption. This is not astonishing if an examination of the nose, pharynx

or throat is not made or the excretions from the nose and the swollen tissue are not examined, since the patient becomes hoarse, coughs, has expectoration of tough mucus, is dyspneic and slowly becomes cachectic, loses weight and finally succumbs. What could it be if not consumption?"

It may be that here too, in the United States, some of the scleroma cases are accepted for treatment as either syphilis or tuberculosis, the clinical symptoms and the objective appearance of scleroma at certain stages lending semblance to either of these diseases. During the trend of emigration from Russia and Austria, probably including the endemic regions, there was a large influx into the United States from these countries, myriads coming in monthly, among whom it is likely to assume not a few arrived from the endemic districts, infected with scleroma, and therefore it is surprising, that up to 1908 only 16 cases in all have been recognized and reported in the United States, according to Emil Mayer's[49] tabulated cases, and this during a period of 14 years.

In view of this, it is more than likely that the diagnosis of scleroma of the upper respiratory tract is not as readily made as some of the authors so confidently assert, and this is borne out also, aside from the symptoms and appearances, when we recall that the histopathological findings are not pathognomonic for this disease alone, but are found as concomitants of many diseases; and while it is true that some or even most of these diseases are foreign to the upper respiratory tract, yet a few in which similar pathological conditions are found, are frequently met with in the nose and throat to wit, malignant disease, and the two mentioned above. Further, to find bacilli in the tissue may be deceptive, in malignant disease, syphilis and tuberculosis, where a small or superficial piece is examined in the early inflammatory state, either may show hyaline bodies, and foam cells, the stained nuclei of the epithelial or the connective tissue cells may closely resemble bacilli and this easily leads into fallacy. And it must be remembered that the picture varies according to the particular layer of tissue examined. This deception was experienced lately in Dr. Jonathan Wright's clinic on my service; a male, native of Eastern Prussia (scleroma region), aged 34, presented himself with marked huskiness of voice and slight cough, with the arytenoids, edematous, mostly on the inner aspect and above, in color somewhat pale with thickening of the false cords; throat symptoms dating back about one year. Examination of the chest was negative. A small piece excised showed foam cells, hyaline bodies and what appeared to be bacilli. A tentative diagnosis of possible laryngeal scleroma was made; one week later, a larger piece was taken off from the swollen arytenoids and this showed tubercle and giant cells and in a subsequent examination of the sputum tubercle bacilli were found.

The bacteriology of this disease must be proven by growing the Frisch bacillus in a pure culture, from the infected regions, in order to assure a correct diagnosis; yet that this alone is also insufficient is exemplified in Schilling's[50] case: clinically the case looked like scleroma and the histological examination of the tissue proved it as such, but a bacteriological examination from the nose and larynx repeatedly showed pure culture of the diphtheria bacillus and the blood serum of this patient was proved to have immunizing antitoxic properties; ½ c.c. of the patient's blood serum neutralized a fifty-times fatal dose of diphtheria emulsion. Here we had bacteriologically and biologically diphtheria, which we may assume was the secondary process and histologically we had the scleroma as the primary process. Whether the secondary process influenced the course of the scleroma, or whether the Frisch bacillus could have been cultivated from the excised tissue, is not stated.

It is then probably true, that for diagnosis too much reliance cannot be placed upon either the histopathology or the bacteriology, but that these must be combined, with the addition of a consideration of the clinical course or history of the disease, an important factor often given too little attention or at times overlooked. With this triple combination, and by elimination, distinguishing scleroma from the like appearing diseases, a correct diagnosis will be attained.

Differential diagnosis need not be further expounded; anything more than what has been applied here may seem superfluous. Complications are frequent in scleroma; many other infections have become secondary processes as the exanthemata, erysipelas, cancer, etc. A most interesting complication is reported by Wolkowitsch where a carcinoma developed on the nose after it had been afflicted with rhinoscleroma for twenty-six years.

Treatment.—From the time that rhinoscleroma was identified as a special disease, nearly forty years ago, many efforts have been made to alleviate the harassing symptoms as well as to cure this terrible affliction. At first surgery was given full play, but even when exercised in a most radical manner, was soon followed by recurrences. Injections were made of bichloride of mercury, carbolic acid, Fowler's solution of arsenic, and malate of iron, in most cases without effect. To relate all the resorbents and resolvents which were found useless would have only a passing interest. In the following modes of treatment, some authors claim retrogressive results and some even cures. Lang[51] by fairly saturating his patient with the salicylates, using a one and two per cent. hypodermic injection every second day, douching and pencilling, using it as a snuff and as a 5 per cent ointment externally, and clogging the nose with it, and giving internally two grams daily for one and a half months, had reduction and involution take place; prolonging this same treatment, he claimed further good results. Wolkowitsch in early cases derived good results after three months' treatment from the hypodermic injections of 1 per cent. bichloride of mercury solutions as well as with 1 per cent. carbolic solution and a 1 per cent. sublimate ointment used twice daily. Pawlowsky[52] in 1894 published his results with "Rhinosklerin" after an experience of nearly two years, during this time treating two patients. His "Rhinosklerin" consisted of a combination of the toxins extracted by boiling from the agar-agar nutrient material, after washing off the cultures of the Frisch bacillus and a desiccated extract of the bouillon cultured bacilli dissolved in 50 per cent. glycerine and filtering after standing 24 hours. In other portions he used alcohol and ether as solvents and by animal experiments found the cold filtered aqueous glycerinated extract the more potent. By graduating the dose from 0.1 to 3.5 g., using in all 70 injections in the first case, he injected every second or third day, and after the twentieth injection used it daily. He found a reduction of the infiltration without any further spreading—local immunity. This result was also achieved in his

second case. In the beginning the injections created a reaction similar to tuberculin, but milder. His theory is that the rhinoscleroma bacillus causes toxins, which are partly free and partly combined with the circulating albumenous substances which irritate the neighboring cells. The "Rhinosklerin" produces with the albumenous substances of the blood an antitoxin which combines with the toxin of the Frisch bacillus by chemotaxis (*sic*) and so brings about phagocytosis. Zimmerman in 1902 as quoted by Schein made a serum from the sheep and ass but no report of any case so treated could be found. In 1903 Glas[53] recommended thiosinamin, a 15 per cent. alcoholic solution, by injections into the neck and back muscles, giving four injections during a fortnight and one week later the fifth injection, and also gave it by the mouth. He used it in six cases and claims cures; it makes the tissue softer and more plastic so that the Schrötter tubes can be inserted into the larynx with ease; he advises preliminary tracheotomy in all laryngeal cases since a dangerous subglottic swelling takes place as a result of drug reaction. He recommends it only as an adjuvant to the mechanical treatment, without which it probably would not improve the conditions. Freudenthal recently tried radium and a culture of lactic acid bacilli without result, as cited by Emil Mayer.

According to favorable reports in latter years the *x*-ray treatment seems to give the best results in this disease. In their chronological order Fittig[54] in 1903, Schein[55] in 1905, E. Mayer[56] of Berlin in 1906, Politzer[57] in 1906, Emil Meyer of New York, Ballin[58] and Lustgarten in 1907, Gottheil in 1908 and Rydygier, Jr., 1909 have reported cases treated with the *x*-ray. Fittig *x*-rayed his case daily for nearly five months, for fifteen minutes, covering the face with sheet lead and leaving the lower part of the nose free, using a soft tube at a distance of 3-5 cm, current intensity 7 amperes with 2 to 3 interruptions per second, with good results.

In both of Schein's cases the good effect of this treatment was seen in the nose but did not affect the pharynx; he says the *x*-ray has an elective influence. In discussion Baumgarten asserted "that it affects the nearby process but not the deep seated one." It seems to be the concensus of opinion to use a soft tube, covering with sheet lead with a window cut out, large enough to have the rays act on the diseased parts. In discussing Ballin's paper, Stern recommends short exposures with high frequency rather than long exposures with low frequency, exposing from 3 to 5 minutes at a distance of 3 to 4 inches, three times a week. Politzer's and Ballin's cases were mostly external. E. Mayer of Berlin treated two cases, externally and internally (by oral opening) with the *x*-ray averaging about 12 minutes for each seance, without any local reaction but with disappearance of the growths.

Lustgarten in 1907 reports a case of primary laryngeal scleroma in a girl 18 years old, in which after one exposure to the *x*-ray the dyspnoea became so great that the larynx and trachea had to be opened by an incision 2½ to 3 inches in length; the wound was retracted and the *x*-ray applied to the larynx direct. The first two exposures were made under an anaesthetic, the other applications without it; the tumor disappeared almost entirely after only 6 or 7 exposures. Emil Mayer of New York in 1909 also reported a case with laryngeal involvement, exposing by incision the larynx and trachea and applying the *x*-ray in about the same manner with apparent cure, and no recurrence after more than a year. Rydygier, Jr., recently reported fourteen cases treated by Röntgen rays, remarking that he reported an *x*-rayed case in 1902 before the Congress of Polish Surgeons; he states that he has effected complete cures, having observed no recurrence, even for as long a period as six years. He used a medium soft tube, two or three amperes with a 32-volt primary current. Exposures were made daily, for 2 minutes, kept up for 16 days and resumed after 16 days for 12 days more, followed by another interval of 16 days and again resuming, keeping this cycle up in all three or four times. Treatment may take months, one of his cases being rayed for seven months; he urges not to desist too soon.

Surgery proper may be indicated to relieve the distress of the nasal occlusion and pharyngeal narrowing, and is imperative in the laryngeal cases with danger of suffocation, as well as a means for directing the *x*-ray treatment; here tracheotomy or laryngo-tracheal fissure are elective.

Some authors cite cases of spontaneous recovery after attacks of other infections. Toeplitz and Kreuder[59] say, cases are on record where the scleroma disappeared after fever of long duration, exanthematic typhus and erysipelas. In Lubiner's[60] case it vanished after an attack of typhus. In this connection it would be interesting to know, what effect would be had with an erysipelatous antitoxin serum in scleroma.

Before the writer was conversant with much of the literature here cited, he determined to attempt an autogenous vaccine treatment, since the *x*-ray had failed to improve the patient's condition and the Frisch bacillus was so easily cultivated. The positively good result in the first case, at least for nearly a year, can only be ascribed to the vaccine treatment; a slight recurrence in one nostril only occurring after the patient had left the hospital and become irregular in attendance for inoculations. Upon the second case the vaccine treatment had less effect, causing no regressive action but seemed to stem further invasion. Why so great a difference in result is observed in these two cases under the same treatment is difficult to say unless a certain personal equation comes into play along with a variation in the degree of virulence of the scleroma infection, as is often known to be the case with infectious diseases. With so limited an experience it is not intended to bring the vaccine treatment forward as a positive cure for this disease, although there seems reason to deduce, that continued for a long period and frequently applied a cure would be effected by the vaccine treatment alone. Preference should be given the *x*-ray treatment on account of its easy, painless administration and its more rapid effect; vaccine injections are somewhat painful and would have to be used frequently and for a longer time aside from the consideration that the preparation of a vaccine requires much time, many tedious and exacting laboratory steps; however, where the *x*-ray is unavailable, vaccine could be used or it might be useful as an adjuvant to the *x*-ray, the ultimate improvement in either mode of treatment being probably due to a local leucocytosis this bringing about phagocytosis and local immunity.

Duration and Prognosis.—The duration of scleroma is variable, cases having been diseased for as long a period as thirty years; the prognosis in regard to life, up to a short time ago, has been a relative one depending upon the parts affected, hav-

ing been particularly bad when the larynx was involved. Since the *x*-ray treatment has been advanced and proven an efficient therapeutic measure in this disease, and with the added local immunity, if no more, that can be brought about with vaccine therapy, as instanced in the two cases here recorded, much of the horror of scleroma is relegated to the past.

Report of Cases. Case I.—Harris Saltzmann, single, aged 19 years, native of Minsk, in Western Russia; in United States 3 years, came to Dr. Jonathan Wright's clinic at the Manhattan Eye, Ear and Throat Hospital, December 5, 1907; two months previously he was treated at the Mt. Sinai Hospital for rhinoscleroma, *x*-rayed for four weeks with slight improvement in breathing. Tissue from his nose presented the usual appearance noted in scleroma, and bacilli were isolated from the exudate, having cultural characteristics of the Frisch bacillus. Diagnosis confirmed. Physical condition: healthy appearance, well developed, the nose deformed and enlarged, tissues of the upper respiratory tract showed a general thickening, abdomen and chest negative, hands cold and cyanotic. Family history negative. Personal history: had the common diseases of childhood; when seven years old he was under treatment for some nasal condition and from that time had nasal swelling, which became worse in snowy weather; gradually the pharynx and larynx became involved, and at times he had great difficulty in breathing and swallowing; slight exertion caused dyspnea. No specific history, no trauma. Nose has been enlarged for ten years across the bridge but has not increased during the past two years. For the past six months the patient is hoarse and coughs. The sense of smell is intact. Local examination: aside from the external enlargement, both nostrils were almost entirely occluded with a pale, fibrous-looking mass; the pharynx was thickened and dark red, the nasopharynx narrowed, the tonsils and pillars enlarged; the cords and ventricles of the larynx were thickened and red, with a marked subglottic growth appearing about like the ventricular bands above, but thicker and denser, leaving a small narrow slit. The glottis has been partly covered with a gray and tenacious membranous secretion which, from time to time, was thrown off by coughing. Treatment: He was *x*-rayed for two months tri-weekly with no improvement. Laryngeal stenosis becoming greater with alarming dyspnea, the patient was admitted to the ward and a low tracheotomy performed on March 10; the trachea as observed through the wound was normal; after 24 hours the steam tent was removed and on the third day the patient was up and comfortable. April 19, outdoor recreation for two hours. April 21, complained of ear ache (left) and the next day a paracentesis was done. April 23, the ear showed a foul, yellowish discharge; the usual treatment was instituted and the discharge ceased on April 28. It may be mentioned that a culture from the discharge was negative for Frisch bacilli. On May 26, '08, the patient received his first injection of 1 c.c. = 250,000,000 dead bacilli, in the subscapular region, without any reaction, opsonic index before injection 0.6. In the beginning the injections were made in the morning in order better to observe any reaction, either local or subjective. May 30, index 0.6+, and a second injection of 1 c.c. was made with a decided reaction following—temp. 99.4° F., pulse 106, respiration 24, with profuse perspiration; dizziness, insomnia, general nervousness, and pains and stiffness of the muscles lasting through the night, the patient remaining in bed the next day of his own volition. June 1 he complained of pain in back and nose; June 8, index 0.7, he received the third injection, having the same reaction, with bloody discharge from nose; June 9, index 0.9; June 17, index 0.8; June 18, 1½ c.c. = 375,000,000 dead bacilli, was injected without any reaction. On June 27, index 0.8+, 2 c.c. = 500,000,000 bacilli, were injected with some reaction, perspiration, and general malaise; June 28, has expectorated a blood stained, thick discharge for past twenty-four hours, with bloody nasal discharge; June 30, index unsatisfactory; July 4, index 0.9+; within this recorded time the patient gradually felt better in a general way, had improved nasal breathing and a decided shrinking of the nasal mass and that of the larynx, a view of the cords being now possible, the voice became stronger, and the breathing easy with a finger over the tracheotomy tube; July 5 the tube was removed permanently. It was interesting to note about this time that the Frisch bacillus could not be cultivated from the nose after repeated trials; it, however, being necessary to get a culture to replenish the old supply of vaccine, on July 14 the tonsils were removed with a cold snare and from this fresh surface a culture was obtained from the exuding blood. The opsonic indices were now omitted but the injections were kept up, increasing the dose now and then to 4 c.c. = 1,000,000,000 dead bacilli, and, with each a reaction was noticeable, but not so marked as in the beginning. During August the patient showed further improvement in the local condition. On September 14 another index was taken and found to be up to 1.12. October 2, '08, the patient was discharged from the hospital by his own request. After leaving the hospital the patient's visits to the clinic became irregular, once a week, rarely twice, but on each occasion he received a vaccine injection, now for convenience selecting the arm for these inoculations. In the pursuit of my reading on scleroma it was seen that many writers reported excellent results from the *x*-ray, and in justice to the patient, after November 19, '08, this was added as a weekly seance. This, however, up to date has not shown as flattering a result as it was reasonable to believe it should. On the contrary, early in February of this year a slight recurrence was noticed in the right nostril. This was ablated on February 23, '09, and the condition of the patient is as you see him to-night, with a good deal of retrogression of the infiltration, no dyspnea on exertion, and he is able to earn a livelihood. He has had in all forty-three injections, no abscess formation at point of injection, and no untoward effect other than the reactionary disturbances.

The technique for the opsonic index and vaccine treatment has been described in full in many journals and is included in all recent works on bacteriology and hematology, and is in full exposition in Allen's[61] text book.

It suffices to mention here that the vaccine was prepared from cultures of the Frisch bacillus grown in tubes on slant agar-agar for twenty-four hours, cultures flooded off with normal salt solution, standardized as to the number of bacilli per c.c., and diluted with normal saline. The cultures were killed by exposure to a temp. 65° C. for one hour and with the addition of 0.5 per cent. lysol as a preservative, the vaccine was ready for use. The vaccine in these two cases was standardized to 250,-

000,000 bacteria per c.c. An autogenous one, being the most potent, was used in each case.

The opsonic indices were carried out for about six weeks, but often were found unsatisfactory, and thereafter the injections were made without this exacting calculation. It is now a common understanding among workers in this field that one can be guided entirely by the clinical symptoms. Numerous blood counts were made, and in both cases, showed a marked increase in the number of leucocytes after a few weeks' treatment (over 3,000 in both cases). Urinary examinations showed nothing of interest.

Case II.—This case came to my service in the clinic, by the courtesy of the chairman of this section of the Academy, Dr. Harmon Smith. The patient was first seen by him at the Manhattan Eye, Ear and Throat Hospital on July 9, 1908; she was transferred by Dr. Smith with a diagnosis of rhinoscleroma and put at my disposal for the vaccine treatment. The patient, Helen Bialonovszka, is married, aged 25 years, native of Seedeltz, Russian Poland, in United States one year. Physical condition: frail, anemic, cachectic woman; some nodular deformity of nose, with the nostrils anteriorly almost closed and a raised, moist infiltration on the upper lip, extending about one-half inch downward from the right nasal wing. Abdomen and chest negative, the hands cold. Family history negative. Personal history: she lived in her country town for sixteen years, was married at seventeen, and has had five full term pregnancies, two children living and well, three died in infancy; eight years ago she had diphtheria for two weeks, and two years after this, in Warsaw, polypoid growths were snared out of both nostrils on account of difficult breathing; one year later the nose again became clogged and another operation was performed but the clogging soon returned. Thereafter the nasal breathing became more difficult and two years after the nasal trouble began the cutaneous lesion appeared. The nose at times is painful and often bleeds, but olfactory sense has been preserved. Local examination shows nodular deformity of the right side of the nose; the right nostril has a pin opening surrounded by a pale infiltrated mass, with a round, raised, cracked, red infiltration extending from the nasal wing one-half inch downward on the lip. The left nostril has a slit opening about one-eighth inch long, the rest is filled up with the infiltrated mass. The tonsils and pillars are grown into one compact mass, dark red in color, extending back to the pharyngeal wall and coming together to within about three-quarters of an inch; a cicatrical adhesion of posterior pillar and pharyngeal wall is to be seen on the left. The nasopharynx is almost entirely obliterated making it impossible to examine the post nasal fossa; the uvula is absent and the soft palate is raised upward and backward; a granulated nodular mass, mottled red and white in color, covers the hard palate, extending forward to a line drawn across the second molar teeth. The larynx is free. The right ear has an O. M. P. C. of some years standing, with little discharge but at times is painful.

Treatment.—The patient was admitted to the ward and during the next month it was attempted to improve her general condition by good nourishment, rest and tonics, but she could not be persuaded to stay more than three or four days at a time. On August 3, index 0.5+, she received an injection of 1 c.c. = 250,000,000 dead bacteria, with practically no general reaction, but a marked local reaction, very profuse blood-stained nasal discharge, sore throat, pain over bridge of the nose and clear nasal bleeding, and some malaise. August 13 she received the second injection of 1 c.c. = 250,000,000 dead bacteria; the temperature rose 1° within two hours; general malaise, marked frontal headache, soreness of all muscles, especially on the left side (injection); locally pain over the nose, sore throat, blood-stained nasal discharge, and marked diaphoresis with weakness. On August 20, index 0.67, an injection of 1 c.c. = 250,000,000 dead bacilli was given. Some local reaction was present. General reaction was more marked, and the patient quite prostrated. On August 22, index 0.6+ (unsatisfactory), the patient became very restless and at times was moaning; had frontal headache and pain in the ears; the area of nasal disease was more inflamed and painful. On August 31 the general condition was better, but the local condition unimproved. Index 0.75 and an injection of 1½ c.c. = 375,000,000 dead bacteria was made, and within a few hours the patient complained of severe pain in the head and neck, had general malaise and profuse sweating. September 14, index 0.9, an injection of 2 c.c. = 500,000,000 dead bacteria was given and the patient went home. On her next visit to the clinic, she said she had intense headache and dizziness the day after the injection. September 22, the patient did not report. From thence on she appeared at the clinic regularly two or three times a week. This woman received in all thirty-two injections, with no abscess formation. As in the former case the indices were now omitted, and the injections made about once a week, rarely twice, and now and then the dose increased up to 4 c.c.; though it cannot be said that the disease has in any way decreased, yet it has not advanced and the patient's general condition is greatly improved. During these eight months she has taken the Elix. ferri, quiniæ et strychinæ cit., t.i.d. In this case too, from about the middle of November on, the disease was exposed to the *x*-ray twice or thrice weekly in the usual manner, without any appreciable benefit up to date. One month ago the left nostril was freed from the infiltrated mass with the knife and the curette, and at this time a septal perforation came to view extending well back, but whether it antedates the scleroma disease cannot be determined. The nasal caliber was held patulous for a while with rubber tubing, but on its removal it has again almost entirely closed up. The cutaneous lesion was ablated and recurrence was also rapid. Excepting her general improvement, her local condition to-night is about as it was when first seen at the clinic.

Conclusions.—From what has been presented in this paper, the following conclusions may be drawn:

1. That scleroma is an infectious disease, whose onset has occurred even in infancy, but usually begins in childhood or adolescence and it is not limited to adult life, as some still believe.

2. That the so-called Frisch bacillus plays an important rôle in the causation of scleroma, being found in the exudate and in the tissue proper, and my work, proving that a vaccine prepared from the Frisch bacillus can create at least a local immunity, is a further point favorable for the aetiogenesis of the Frisch bacillus is this disease.

3. That the Frisch bacillus in the tissue is also Gram positive, when hardened in a 5 per cent. formalin solution as observed by the writer.

4. That the Frisch bacillus has a lively and

lasting motility when examined in the hanging drop, and that the Frisch bacillus grows smaller and thinner as the age of the culture increases, as observed by the writer. From the agglutination test, also applied here for the first time, with the Frisch bacillus, no conclusion can be drawn. Further tests on patients whose immunity has not been influenced by inoculations, might prove valuable.

5. That in the biological experiments the time factor has been overlooked, and, in the future, in so chronic an affection as scleroma, a long time for observation must be allowed.

6. That, as the writer believes, a parasite or insect may be the means of transmission for this disease and when discovered will supply the missing links for the infectious etiology of scleroma.

7. That even allowing its contagion to be mild, at some time the emigration or health authorities in the United States may have to adopt means to limit the increase in scleroma cases.

8. That the examination of a small piece of tissue leads into fallacy in histopathological diagnosis; therefore examine as large a piece of tissue as possible.

9. That a deformed contour of the external nose is only found in a small percentage of cases.

10. That metastasis does rarely occur in scleroma.

11. That the diagnosis of scleroma, at least in the early stages, is not easily made, and that the clinical course must be taken into consideration along with the bacteriology and histopathology in order to arrive at a correct diagnosis.

12. That scleroma does not render a patient immune to other infections, but that other infections may favorably antagonize the scleromal process.

13. That the *x*-ray treatment, at this time, holds out the best prospects of a possible cure for scleroma: that the vaccine treatment has at least caused a local immunity, and may be a means of possible cure if used for a long time, and, as to frequency and quantity, in proper dosage: and that with no criteria to guide my original work in this disease, these points in the vaccine treatment still need to be worked out; and that surgery has only an elective place in the treatment of scleroma and is useful only as an auxiliary.

Grateful acknowledgment is herewith tendered to Dr. Jonathan Wright and to Dr. Harmon Smith for their kind encouragement; to Dr. Edwin C. Zabriskie for the accompanying photographs and the photomicrograph; to Dr. James C. Dwyer, late house surgeon, for his valuable laboratory assistance; to Dr. F. M. Law for his patient *x*-ray treatment of these cases and to Mr. Samuel Richardson, laboratory assistant, for his frendly cooperation in the pathological work.

BRAIN ARCHES.

FOUR GRAND ARCHES OF THE CEREBRUM.

By WALLACE WOOD, M.D.,
NEW YORK.

The cerebrosphere presents parallels of latitude and parallels of longitude. Here is the grand verity. The parallels of latitude have already been published. We take to-day the parallels of longitude. Working for the last fourteen years upon the cortex of the brains of men and animals by the special method of painting homologous lobules and gyri, either upon the dry mummy or upon the plaster cast, I sought to generalize the various types or to arrive at a truth which might be of utility in the study of the morphology of the cerebrospheres of man.

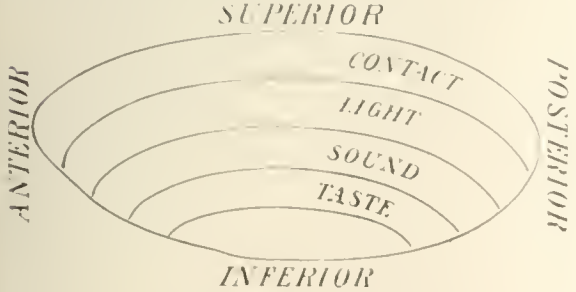

Fig. 1.—Primary arches of impress.

The truth I have been able to demonstrate, as I believe, is that in final analysis the human cerebrum in form consists of four grand rings or arches surrounding the limbus, limbic lobe, or rhinencephalon.

Comparative anatomy is a new science. Comparative gyrology or the comparison of the convolutions of the brain in man and the other gyrencephala is yet unborn, since there is no text book, and the usual bibliography beyond Leuret and Gratiolet, Meynert, Broca, Krueg and Andrew Parker is not voluminous. The four types of cerebrum, say ox, dog, bear, man, look at first unlike. Compared carefully, however, by taking the dry specimens or casts and painting homologous gyri, it will be found that they are reducible to one general form, and that form one of great simplicity. It is nothing more or less than a hemisphere surrounded by four rings or arches.

It is easy to demonstrate this type in the dog, and felines follow. Man at first seems not at all to conform to this longitudinal type. The link which unites the two is the brain of the ox.

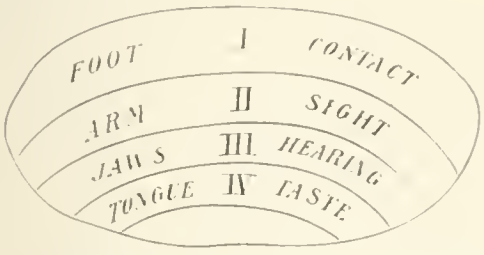

Fig. 2.—Generalized scheme for cerebrum of dog and ox. The cerebrum consists of four grand rings, arches, or zones around the limbus or rhinencephalon.

Compare bovine with canine brains and one will find each to consist of four great rings surrounding the limbus or rhinencephalon. Bovine conforms to canine.

At the posterior pole then, four rings, counting from inferior to superior, are zones of taste, hearing, sight and contact.

What are these arches in front? They appear to be, counting from inferior to superior, centers for tongue, jaws, arms, legs.

Hearing is in line with the jaw, *maxilla*.

Sight in line with the arms, *manus*.

Contact in line with the hip or foot, the *pes*.

Next compare the ox and man and you will be astonished to find how much these two best of all the creatures have in common when we arrive at the pith and nucleus, the soul and center, that is to say, the cerebrum.

Compare the cerebrum of the dog with man and you can not find the four arches in man. Compare the cerebrum of man with the ox and you have in the ruminant an interpreter.

Can the human cerebrum be reduced to four grand longitudinal arches? Dissection of the brains of fifty cattle and examination of the brains of two hundred men answer the question in the affirmative.

FOLLOWING IS THE DEMONSTRATION.

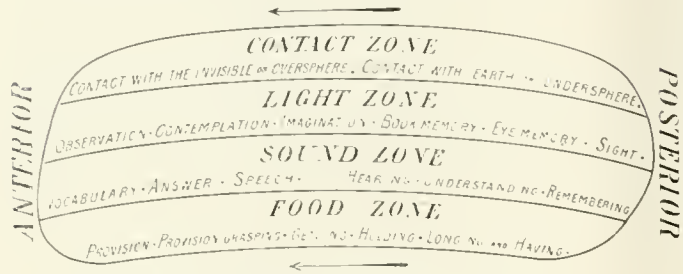
Arch No. I, the marginal gyrus, is comparatively easy. The metopic, paracentral, precuneus and cuneus lobules are all demonstrable in the bovine, the proportions strangely altered.

Arch No. II in man comprises the second frontal gyrus, the medicentral lobule, the angular gyrus, and the occiput. The angular gyrus is the stem of the occiput. The angular gyrus is the stem of the occipital eye-bulb, apparently crowded out of its connection with the manus lobule and has joined the ear lobule, thus uniting auditory and visual areas.

Arch No. III is the third frontal with the infracentral and the first and second temporal. Here the ox gives us the clue; we should not have guessed that the first and second temporal were one arch, one long gyrus, without his help.

Arch No. IV comprises the gyrus rectus apparently, the insula and the third temporal. The human cerebrum is thus straightened out and greatly simplified.

If this four-arch scheme is constantly borne in mind, I think it will be of help both in the study of form and function.



CONTACT ZONE
CONTACT WITH THE INVISIBLE OVERSPHERE. CONTACT WITH EARTH UNDERSPHERE.
LIGHT ZONE
OBSERVATION · CONTEMPLATION · IMAGINATION · SOUL MEMORY · EYE MEMORY · SIGHT.
SOUND ZONE
VOCABULARY · ANSWER · SPEECH · HEARING · UNDERSTANDING · REMEMBERING
FOOD ZONE
PROVISION · PROVISION GRASPING · GETTING · HOLDING · LONGING AND HAVING.
ANTERIOR
POSTERIOR

Fig. 3.—Diagram of the four cardinal brain arches, indicating the progression from posterior to anterior and from impress to express.

Comparative gyrology I believe to be good. The most interesting work I have ever done is to take the brains of ovines, bovines, chevelines, canines, felines, oursines, and primates, and straighten out the kinks and coils until I arrived at uniformity. Amid all the variety and complexity there runs the silver thread of divine simplicity. Noble, dignified, sublime, supernal, celestial; it is worth more than all our epithets.

The human brain is a simple, noble, accurate, symmetrical, intelligible sphere. Grand, indeed, is its simplicity and perfection. You draw a half oval and you divide it into five rings or arches—that is, four upon one. This is the cerebrum simplified.

Nothing more beautiful, these are the rivers of sense flowing into the restless sea.

The river of scent is the lowest ring; the river of sap, sapidity or flavor is the second ring; the river of sound is the third; the river of light and imagery is the fourth; the stream of tactility and mobility which we call the outer world is outermost and uppermost.

These parallels of longitude are to be borne in mind as related to each other.

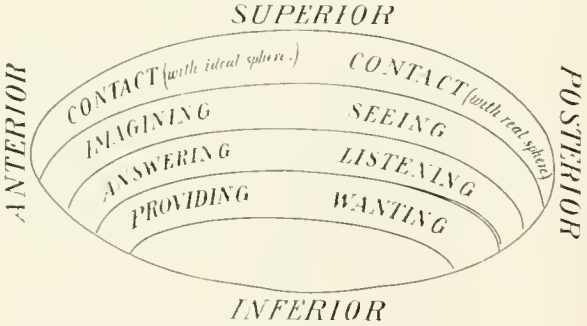


Fig. 4.—Cerebral arches of impress and express.

The inferior arches mean food, inwardness; the superior arches mean contact, work, outwardness, light; sight is a spiritual outwardness. Thus the sphere is divided into an inwardness and an outwardness.

The sphenoidal pole, the temporal lobe, is the orecticon, the spirit of food longing and food having.

Further toward the front must be the lobule of food getting, and still further front the lobule of sagacity or the wisdom of food getting.

Want and desire, longing and having, getting and keeping, grasping and holding, provision and previsions. This is the chain. Food and drink are material. Houses and lands and cattle and heaps of gold and silver are not spiritual. The sciences of medicine, agriculture, engineering, commerce, are material, not spiritual.

The next arch is the line of the inner spiritual, for sound is intimate, and sound is spiritual.

Food and music make a wedded pair; eating and drinking, music and conversation go well together.

The zone of sound presents two or more lobules posterior and two or more lobules anterior.

Posterior are the ear of hearing, the ear of understanding, and the ear of memory. Anterior are the answering tongue and the head or cap that frames the answer, and doubtless the personal vocabulary out of which the words are selected.

The arch of light is above that of sound. It is long and varied. We find in it three posterior centers—the center of sight, the center of visual memory, the center of compound memory, memory of written words, eye of sight, eye of memory, eye of book memory in men, and at the anterior extremity the center for writing, the eye of imagination, the eye of contemplation, the eye of observation.

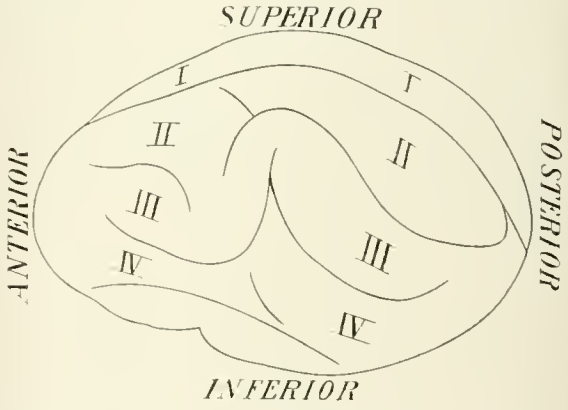

Fig. 5.—Four arches in the brain of an ox.

Posterior are:	Anterior are:
I. Contact.	I. The pes.
II. Sight.	II. The manus.
III. Hearing.	III. The maxilla.
IV. Taste.	IV. Tongue or larynx.

Just as the outer eye and ear form the acme of the face, so the sound zone and light zone make the acme of the cerebral sphere.

The crown area consists mainly of four lobules—two posterior, two anterior—and by the posterior

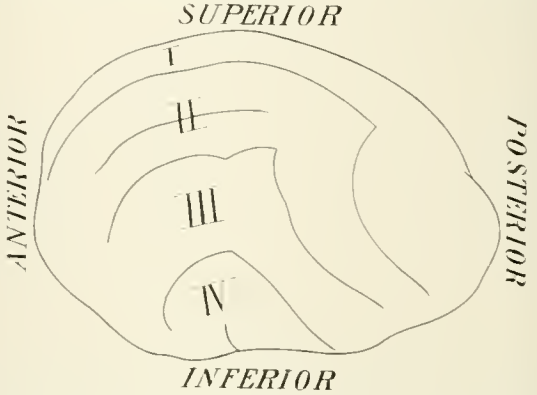

Fig. 6.—The four grand arches on the brain of a dog. All cerebrums of the gyrencephala are reducible to this general form.

two we appear to have contact with the earth, and by the anterior two we appear to have contact with heaven.

Having demonstrated the brain segments and the

brain arches the following question arises: If the cerebrum is a sphere formed by a spherical intelligence, if these strangely beautiful, strangely intelligible parallels of latitude and parallels of longitude are formed by the laws of nature or the laws of God or the laws of the gods, then have we not a sure foundation for something above sense as astronomy is above "sunrise?"

Have we groundwork or framework for an encephalonomy?

THE RARE FORMS OF CYANOSIS: POLYCYTHEMIA, METHEMOGLOBINEMIA, AND SULPH-HEMOGLOBINEMIA.*

By T. WOOD CLARKE, M.D.,

NEW YORK.

Cyanosis is, of course, not in itself a disease, but a symptom which occurs in many and various diseases. With the common conditions in which it appears, all are familiar. On the first sight of a patient with lips, face, and fingers blue, the mind at once jumps to the question: Is it heart or lungs? In the vast majority of cases this immediate narrowing of the possibilities is justified, and a physical examination will reveal heart disease, pneumonia, pleurisy, emphysema, asthma, or tuberculosis. In these cases the color is due to improper circulation or imperfect aeration of the blood, and is always accompanied by a weak or irregular pulse and a rapid or labored breathing.

Occasionally, however, cases are met in which the patient, while apparently fairly comfortable, with a regular pulse of 70 to 80, and an easy respiration of 18 to 20, presents an appearance of cyanosis of a most startling degree, a blueness, almost black, of the mucous membranes, and a color of the skin suggesting gun metal. In these cases one is surprised to find that a physical examination shows the organs to be healthy and acting in a normal manner. In such cases the question arises what to do to clear up the cause of the patient's extraordinary appearance. The immediate cause of all cyanosis lying in the blood, the first step should be to make a blood count. This will, in certain instances, give valuable information, especially if the red blood count is above normal.

In 1903, Dr. Osler[1] called attention to a disease, which he called polycythemia, reported three cases, and collected a few more from the literature, in which there were four striking characteristics—marked obstinate constipation, an enlarged spleen, a very high red blood count, and cyanosis. This has now become recognized as a definite clinical entity, and last year, Professor Anders[2] was able to collect from the literature fifty-three such cases. It occurs especially frequently among Hebrews of middle age. The red blood count varies from seven to twelve millions, while the hemoglobin is estimated from 110 to 200 per cent. The leucocytes are usually not above normal. The condition persists for years, and treatment seems to do little for it. The patients go regularly about their work, and, though somewhat weak and tiring easily, feel no especial effects other than those ordinarily accompanying chronic constipation.

When the ordinary blood count fails to reveal the cause of the patient's cyanosis, we have still one further diagnostic aid in solving the puzzle, an aid which is sadly neglected in the teaching of even the best medical schools. I refer to the spectroscope. This instrument, though simple in its use, and, in its smaller forms, inexpensive in cost, is to the vast majority of the medical profession a mystery. In our courses in physiology the student is shown the various blood pigments as produced in the laboratory, and probably for a day takes a fleeting interest in the pretty colors shown him. There, however, his education ends, and by the time he has reached the stage of diagnosing disease he may have a hazy idea that oxyhemoglobin and reduced hemoglobin can be told apart, and that methemoglobin and carbon-monoxide-hemoglobin do exist, but I should be greatly surprised if twenty-five per cent. of the senior students of even our best medical schools could tell how to distinguish between them, and even fewer be able to recognize them at sight. Still it is the use of the spectroscope which gives the easy and the only means of diagnosing the class of diseases which I will now describe.

I have spoken of the cyanosis produced by faulty aeration of the blood, and of that occurring in conjunction with a high red blood count. I now wish to take up the rarest of all forms of cyanosis—those produced by alteration of the blood pigment itself. You know that the red color of the arterial blood is caused by oxyhemoglobin, and the blue color of the venous blood by reduced hemoglobin, the reduction consisting of a displacement of an atom of oxygen by carbon dioxide. On rare occasions, however, other pigments may appear, which, changing the color of the blood, alter the patient's appearance. The most common of these is methemoglobin, a brown pigment probably formed by a rearrangement of the oxygen atom in the molecule. It has long been known that certain drugs given in poisonous doses will cause this change, and produce a pronounced cyanosis. The most common of these is acetanilid, the basis of most of the headache powders on the market. The other similar products, as phenacetin, sulphonal, and trional, and also potassium chlorate, nitrites, and many other poisons will produce the same results. These forms of poisoning, either acute or chronic, are characterized by marked cyanosis, with, unless the dose has been sufficient to cause coma or death, few constitutional symptoms other than headache and prostration. The heart and lungs are usually quite normal, and though the temperature may be subnormal, the illness is often first noticed by the patient's friends. When, therefore, one meets such a case, he must inquire thoroughly into the history of the taking of drugs, especially of headache powders, and of the patient's occupation, for workers with the drugs, as well as artisans in the analin factories, are very prone to the poisoning. He should then confirm his diagnosis by taking a little of the patient's blood and finding the methemoglobin by use of the spectroscope. The treatment in chronic cases consists in stopping the drug, and in acute cases in lavage, or emetics, fresh air, warmth, and cardiac stimulants.

This was practically the extent of my knowledge of cyanosis two years ago, when I was asked by Dr. Garrod, Lecturer on Chemical Pathology at St. Bartholomew's Hospital, in London, to undertake some investigations of a case that was puzzling the physicians of that institution. The patient was an unmarried woman of thirty-seven, who had been ill for eighteen months with marked cyanosis, debility, and constipation. Early in the attack a diagnosis of thoracic aneurysm had been made and a hopeless

*Read before the Passaic County Medical Society, Paterson, N. J., Feb. 9, 1909.

prognosis given. She had not died, however, and in the fall of 1906 was sent to St. Bartholomew's Hospital and put under the care of Dr. Samuel West. The examination showed a woman extremely cyanosed, but with heart and lungs normal, pulse and respiration quiet. The blood count showed 4,800,000 red cells, 3,800 leucocytes, and 90 per cent. hemoglobin. Though the taking of drugs was absolutely excluded Dr. West had a spectroscopic examination of the patient's blood made by the professor of physiology, who reported that methemoglobin was demonstrated. The entire visiting staff of the hospital was consulted, but no satisfactory explanation of the patient's striking condition could be offered. At this point Dr. Garrod was appealed to to undertake some chemical investigations, but as he could not give it the time, he kindly offered me the opportunity.

A search of the library of the Royal College of Surgeons revealed a small literature on the subject, emanating mostly from Holland. The first case of idiopathic or enterogenous cyanosis due to methemoglobinemia was reported in 1902 by Stokvis,[3] of Rotterdam, and much investigation was done on this and seven subsequent cases. The patients had all suffered from chronic diarrhea, and had been markedly cyanosed. The methemoglobin was found by Talma[4] of Utrecht to occur in the corpuscles only, the serum being clear. It remained for Hijman van der Bergh[5] and Gutterink[6] of Rotterdam to prove the presence of nitrites in their patients' blood. As this chemical is a powerful methemoglobin-forming poison, they believed that the absorption of nitrites from the intestines was the cause of the disease. Gibson and Douglas[7] of Edinburgh, however, in one case reported by them under the title, "Microbic Cyanosis," believe the condition to be due to a blood infection by the colon bacillus.

Besides these eight cases of methemoglobinemia, four closely allied cases were reported by Van der Bergh. In these the cyanosis was the same as that in the other eight cases, but the patients differed in that they were constipated. In the first case of this series, the author thought that he was dealing with a case of methemoglobinemia until he noticed that the characteristic absorption band in the red part of the spectrum was slightly nearer the yellow than it should be. Extensive researches demonstrated that the spectrum was not that of methemoglobin, but corresponded in every way with that of sulph-hemoglobin, a purple pigment obtained by treating blood with sulphureted hydrogen. He therefore called his case one of sulph-hemoglobinemia. The two spectra are very similar, but can be distinguished instantly by treating the blood with ammonia or ammonium sulphide, which causes the methemoglobin band to vanish, while that of sulph-hemoglobin is not affected. A further distinction between the two diseases lies in the fact that if a methemoglobinemia patient is put on a pure milk diet the cyanosis clears up in forty-eight hours, and the methemoglobin disappears completely from the blood, the whole symptom complex, however, reappearing within four hours after a full meal. This temporary improvement does not occur with sulph-hemoglobinemia.

In beginning our work on this case we at first familiarized ourselves thoroughly with the spectra of the various blood pigments, especially those of methemoglobin and sulph-hemoglobin made from ox blood. During these preliminary experiments it was found that if sulph-hemoglobin were treated with carbon monoxide, a new compound with a new spectrum was formed which it seemed well to call carboxy-sulph-hemoglobin. Methemoglobin was not affected by carbon monoxide. This observation supplied us not only with a new confirmatory test for illuminating-gas poisoning, but also with a new method for differentiating between the two pigments. An examination of the patient's blood on two occasions showed the absorption band to be in the position of the sulph-hemoglobin band, to be stable when treated with ammonium sulphide, and to act characteristically with carbon monoxide. We therefore decided that we were dealing with Van der Bergh's disease, sulph-hemoglobinemia and not with methemoglobinemia.

This being determined, we directed our attention to the source of the sulphureted hydrogen. A very delicate test for H_2S tried on the patient's blood was negative. The stools, fermented for twenty-four hours, showed but a bare trace of the gas; while on bacteriological examination they showed no increase in the H_2S forming organisms. The

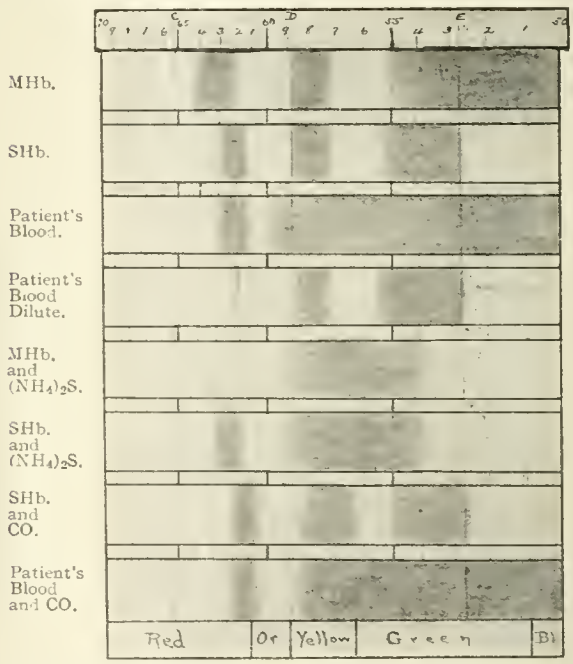

Chart of the absorption spectra mentioned in this article. (From West & Clarke, Medico Chirurgical Transactions, London, Vol 90.)

urine was in every way normal, and showed no increased intestinal putrefaction. A blood culture was sterile. In short, we were quite unable to find any source for the H_2S which had caused such a marked change in the patient's blood.[8] Our later researches into the chemistry of sulph-hemoglobin, however, showed that this compound could be formed by an extremely minute trace of H_2S, acting in the presence of a reducing agent,[9] and it was mentioned as a possibility that the occurrence of sulph-hemoglobin in the blood of the patient was due not to an excessive formation of H_2S in the intestines, but to the absorption of an abnormal poison of the nature of a reducing agent, which, acting in the presence of a minute trace of H_2S, produced the pigment in question. This is purely a theory, and is based on no physiological observations.

The technique of a clinical spectroscopic blood examination consists in the following steps: The blood is obtained, preferably directly from the vein, several cubic centimeters being drawn off. If this is not possible a fairly thorough examination can be

made with a few drops from the ear or finger. The blood must be drawn directly into about twice its volume of distilled water. This lakes the blood and gives a watery solution of the blood pigment. The solution is then filtered several times through one filter paper to remove the corpuscles and fibrin. A few drops of the clear solution are placed in a test tube, or preferably a glass dish or bottle with parallel sides, and examined with the spectroscope by transmitted light. To the specimen distilled water is added drop by drop until the dilution is obtained which allows a good transmission of the red light only. If a black band is seen in the red, the blood contains either methemoglobin or sulph-hemoglobin. If the band persists on the addition of a few drops of ammonium sulphide, the pigment is sulph-hemoglobin; if it vanishes it is methemoglobin. The addition of a reducing agent, as hydrazene or phenylhydrazene, may intensify a sulph-hemoglobin band too faint to be seen otherwise.

To summarize: A case of cyanosis without lesion of the heart or lungs may be due to some change in the blood. This may be an abnormally high red cell content, or polycythemia, in which case it is probably associated with an enlarged spleen and chronic constipation. It may be due to a change in the blood pigment itself. If the abnormal pigment is methemoglobin, the condition may be due to drug poisoning, or autointoxication by the absorbtion of nitrites from the intestines in cases of chronic diarrhea. If the pigment is sulph-hemoglobin, it is probably associated with chronic constipation, and is the result of the hyperformation or hyperabsorption of H_2S, or of the presence in the blood of an abnormal reducing agent acting with a small trace of H_2S. The methemoglobin cases improve as the enteritis is cured, and the sulph-hemoglobin cases recover if the bowels are kept well open.

It may appear at first sight to be a waste of time to discuss classes of cases which must as yet be considered as medical curiosities. It must be remembered, however, that whereas six years ago polycythemia was so considered, now that attention has been drawn to it, it has become a well-recognized disease, appearing more and more frequently in literature. It seems probable, too, that these two diseases, idiopathic methemoglobinemia and sulph-hemoglobinemia, are not quite so rare as they now appear. Within a week after the publication of the article in the *Lancet*, I was invited to see a case at the West London Hospital which had puzzled the staffs of various hospitals for six years. This was easily shown to be another case of sulph-hemoglobinemia, and was reported as such by Dr. A. E. Russell before the Pathological Society of London.[10] Furthermore, since returning to America, three physicians who had received reprints of our article have told me that they have had under their care cases which clinically belonged to one or other of these types, but that lack of familiarity with the technique of spectroscopic blood examination had prevented a definite diagnosis. This paper is therefore presented in the hope that wider publicity will lead to a more general recognition of the conditions and to further study of their etiology and treatment.

Since writing the above my attention has been attracted by an article by Dr. Emil G. Beck[11] of Chicago to the subject of poisoning by bismuth subnitrate. Since the increased use of this drug in large quantities for *x*-ray diagnosis and in tuberculous cavities, there have been reported a number of instances of severe and even fatal intoxications, a characteristic symptom of which has been cyanosis with methemoglobinemia. It has been shown that bismuth subnitrate even in distilled water will give a test for the free nitrate ion, and it is known that certain of the intestinal flora will change nitrates into nitrites. It is probably the nitrite formed in some such manner from the bismuth compound which is absorbed and has the toxic effect on the blood in these cases. A review of the literature of the idiopathic methemoglobinemia cases fails to reveal any mention in the histories of the administration of bismuth subnitrate. As, however, in each case there was a history of dysentery or long standing diarrhea, it is reasonable to suppose that these patients had been receiving the medicament most commonly given for such conditions, and it is quite within the range of possibility that the so-called enterogenous or idiopathic methemoglobinemias were in fact cases of chronic bismuth subnitrate poisoning, possibly resulting from a diseased condition of the intestines or some idiosyncrasy on the part of the patient against the drug. In future cases of this obscure disease the question of the prolonged use of bismuth subnitrate should be given careful consideration in diagnosis and therapeutics.

SECONDARY CARCINOMA OF THE LUNG.

By L. M. WARFIELD, M.D.,

SAVANNAH, GA.

"It is well known that the lung is the frequent seat of the secondary manifestations of this disease (cancer), that it is generally more or less distinctly implicated by the far from uncommon mediastinal tumors, and that it is occasionally also attacked primarily by cancer; it is well known, too, that its cancerous formations may present all varieties between the densest scirrhus and the softest encephaloid, that they may form tumors from the size of the lung itself, down to the smallest miliary granulations, that they may degenerate in various degrees and ways, and simulate tuberculosis and inflammatory deposits, both in the formation of vomicae, and in other important features." These remarks were made in 1860 by Bristowe on the occasion of the presentation of several specimens before the London Pathological Society.

Primary cancer of the lung is a comparatively rare disease, and the diagnosis of the condition presents almost insuperable difficulties. Only rarely is the diagnosis made during life when, as was reported by Demarest, a piece of tissue was expectorated which, on microscopical examination, proved to be a squamous celled carcinoma. The most complete analysis of primary cancer of the lung which I have been

able to find is that made by Pässler in 1896. He collected 70 cases reported up to that time and added 4 personal observations. Since then about 75 more have been reported. In none of his cases was the condition recognized during life. Among 8,716 autopsies in Dresden, there were 545 cases of carcinoma. Five of these were primary and 74 secondary cancers of the lung. He went over the records of 9,246 bodies in the pathological department at Breslau and found four sarcomas and 16 primary carcinomas of the lung. He does not state how many malignant tumors were among the material analyzed.—My case is as follows:

On Sept. 26, 1907, Mrs. A. L. S., aged 51 years, was referred to me on account of a persistent cough. She stated that her sister had died of diabetes and rodent ulcer at the age of 62 years. Otherwise the family history was negative.

At the age of 14 years she had a severe attack of bronchopneumonia which left her lungs susceptible to attacks of acute bronchitis. Of these she had had several. She has had four living children, the youngest of whom is now 14 years old. Following miscarriage, 17 years ago, she had an attack of nervous prostration which lasted almost a year, and left her nervous and easily excited. About the latter part of 1904, a surgeon removed, with an elliptical incision, a small nodule from the right breast, which was diagnosed microscopically an adenofibroma. Within a few months another nodule appeared in the right breast, and on May 15th, 1905, the right breast was removed *in toto*, together with some of the pectoral fascia, and a portion of the pectoral muscles. The axillary glands were also removed. No large area of skin was removed. On microscopical examination the tumor was found to be scirrhus carcinoma. The wound healed rapidly, leaving a clean scar in which there has always been a sore spot. About 18 months ago the uterus was curetted. At times she had attacks that resembled asthma and she occasionally waked up at night with sinking spells. She has been attending to a home as housekeeper, and has had many worries.

She dated her present illness from January, 1907, when she had sore throat, fever, and dry cough, which latter became loose and she raised much sputum. Since then she had been troubled with a dry cough which was worse during the day, was much increased when she became excited, and was worse as a rule after meals. Occasionally she was so nervous that she could not keep still. She had had frequent attacks of hoarseness, which might come on while she was talking, but soon passed away. She had also had fluttering of the heart. During the past summer she had had occasional chilly spells followed, she thinks, by fever. She thought she now had some fever at night and she felt tired and good-for-nothing. Appetite and digestion had been good. She had lost some weight. For some time, whenever she was worried or excited, the right foot felt numb. During the past summer she had had now and again attacks of sudden blindness, "like moving pictures," before her eyes. She said that she was highly nervous, she was subject to fits of depression and had considerable insomnia. Her eyes had been examined and were said to be normal except for hypermetropia, which was corrected by glasses.

The patient had an anxious expression. Her talk was constantly interrupted by a slight dry cough. Her appearance was highly neurotic. Now and then she would lose her voice. The pupils were normal, mucous membranes good color, tongue slightly coated and moist. Her temperature was 99.2 F., pulse 100, good volume and tension, respiration 26 to the minute, jerky in character. No glands were palpable in the neck, groin, or right axilla. There was one gland about the size of a small marble in the left axilla. Running across the right chest from the second costal cartilage to the axilla was a scar curved with the convexity downwards. The scar was smooth and free from nodules. None were felt around the skin. The whole mammary gland had been removed. The chest was slightly rounded, seemed to expand equally. There was slight impairment of the note beneath the right clavicle, but posteriorly the note was hyperresonant. The left side seemed clear except for occasional scattered sibilant râles. The whole right back was hyperresonant on percussion. At the apex posteriorly the breath sounds were scarcely audible, but on deep inspiration a few piping and sibilant râles were heard. Over the right upper front the breath sounds were prolonged and along with the sibilant râles were also a few crepitant râles.

The heart was normal in position and in the quality of its sounds except for the possible slight accentuation of the pulmonic second sound. The abdomen was soft, and no masses were felt. The abdominal organs were not palpable. There was slight tenderness in the right iliac fossa. All the reflexes were markedly exaggerated. The larynx was examined with the laryngoscope. Except for slight redness of the vocal cords, there was nothing abnormal seen. Examination of the urine was negative. A stained blood specimen appeared normal. The cutaneous tuberculin reaction (25 per cent.) was absolutely negative.

Two subsequent examinations showed no further features of interest. The patient then went to Arizona and was not seen until May, 1908, at which time she entered hospital. About February she noticed weakness of the left fingers with itching and tingling of the hand. The left foot soon became weak. This gradually increased until she dragged her foot. There was headache on the right side of the head. Her cough had been persistent. She had had paroxysms during which she gagged and felt as if she could not get her breath. There had been no spitting of blood; the sputum was always scanty and glairy.

Examination of the chest revealed signs of asthma, that is, hyperresonance, harsh respiration and piping râles. The heart was hypertrophied, beating powerfully, and the superficial arteries were palpable. The urine contained a trace of albumen; no casts were found. The left arm was atrophied and partially paralyzed, especially below the elbow. There was weakness of the left leg with flabby calf muscles. The reflexes in both arm and leg were markedly exaggerated. Her mental condition was obtuse; she was forgetful and melancholic. From that time to her death on August 13th, she suffered with distressing attacks of dyspnea. There was a little fever towards the last month, the pulse was always 96 to 108, full and of increased tension. The dyspneic attacks came on irregularly, at times four to eight during the twenty-four hours. Any effort to talk would bring on a coughing spell during which there was asthmatic dyspnea, followed by the expectoration of a slight mucoid sputum. These attacks were exhausting. Numerous examinations for tubercle bacilli were made, but none were found. There was no vocal cord paralysis. About one week before death she complained of pain in the

right side. A dry pleurisy was discovered at the right back. Over the front in the third and fourth interspaces there was very harsh bronchial breathing, and the percussion note was almost tympanitic. Elsewhere no definite signs could be made out. The patient kept her weight fairly well up to several days before her death, when she rapidly lost flesh and strength, the pulse became weak and rapid. She died on August 13th.

An autopsy was done by me at an undertaker's office about four hours after death. Unfortunately, a lack of instruments with which to open the cranium prevented an examination of the brain.

The pathological diagnosis was carcinoma of both lungs and of the right lobe of the liver, chronic passive congestion of the liver, and cloudy swelling of the kidneys. There was no fluid in the peritoneum, in the pleural cavity, or in the pericardial cavity. There were no adhesions on the surface of the left lung, but a few on the pleural and diaphragmatic surfaces of the right lung were fairly firm, but peeled off readily. The lungs were studded throughout with whitish nodules, firm in consistency, varying in size from a bird shot to 5-6 cm. in diameter. From the cut surface of the largest of these a milky fluid could be scraped. The lung was emphysematous along the margins. The inter-lobar fissures were obliterated. The liver was enlarged and firm, and scattered over the right lobe were a number of dense, white nodules, the largest being 4 cm. in diameter. There were none in the left lobe or in the interior of the liver. The lobus Spigelii was almost replaced by a cancer mass. There were no nodules elsewhere. The mediastinal glands were not involved, but the glands at the root of the lung showed metastases. Sections were studied from the lungs and liver; these showed masses of large round cells with oval or round nuclei, and in the lung there was much degeneration of the cancer nodules. In places there was an enormous increase in the fibrinous tissue looking not unlike a scirrhus carcinoma of the breast. This might be interpreted as a process of healing. Where the tumor was rapidly growing, the alveoli of the lungs were full of the tumor cells, there was some congestion in the other parts of the lung, but no area of pneumonia.

Secondary carcinoma of the lung is not an infrequent condition. Judging from the articles in many text-books, the impression is certainly conveyed that it is relatively uncommon. The fact is that it occurs in about one-third of the cases of cancer of the breast, in which the patients die actually of cancer. In the Middlesex Hospital, including the year 1907, there have been 516 post-mortems on cancer of the breast. The lungs were the seat of metastatic deposits in 178 cases. Naturally these figures do not represent the incidence of lung cancer following operations on breast cancers, but they show in how large a proportion of cases the lungs are involved. No other organ is so prone to be the seat of metastatic deposits. I have been unable to obtain any figures showing the frequency of carcinoma of the lung after removal of the primary breast tumor.

It has always been maintained that carcinoma spreads along the lymph channels, while sarcoma produces its metastases by way of the blood stream. Although this may be true in general, there can be no doubt that not infrequently cancer cells are swept by the blood stream to parts remote from the primary growth. This question of the spread of cancer has been most interestingly discussed by Handley.*

*Arch. Middlesex Hosp., 3d Rpt. Cancer Research Lab., Vol. III., 1904.

He speaks of the centrifugal spread of mammary carcinoma. His contention is, that the cancer cells, instead of being swept along by the lymph actually grow along the lymph channels in radii of a circle having the tumor as a center. These lymph channels are to be found in the tissue covering the muscles, the deep fasciæ. It is only here and there that a nodule, for some reason yet unexplained, grows towards the skin. If, therefore, cancer spreads in such manner, it is not sufficient to dissect out the axilla, but one must also remove the deep fascia within the circle having the distance of the center of the growth to the farthest axillary dissection as a radius. This would include tissue on the opposite side of the sternum as well as that over the upper part of the abdomen.

"Though the area of disease extend from cranium to knee, breast cancer in the broad sense is a local affection, and there comes to the surgeon an encouragement to greater endeavor with the cognition that the metastases to bone, to pleura, to liver, are probably parts of the whole, and that the involvements are almost invariably by process of lymphatic permeation and not embolic by way of the blood. Extension, the most rapid taking place beneath the skin along the facial planes, we must remove not only a very large amount of skin and a much larger area of subcutaneous fat and fascia, but also strip the sheaths from the upper part of the rectus, the serratus magnus, the subscapularis, and at times from parts of the latissimus dorsi and the teres major. Both pectoral muscles are, of course, removed."*

Handley maintains that it is not essential to remove a wide skin area. He gives some suggestive statistics from the operating results of Cheyne and Halsted, the former removing widely the fascia, the latter removing the fascia only beneath an enormous skin dissection. Cheyne's after results seem better than Halsted's.

In a recent study of primary operation for breast cancers, reported in the *Annals of Surgery*, July, 1907, there are some interesting statistics, a few of which will here be given. Halsted traced 210 cases, of which there were 89 cured cases, *i.e.* they were alive and well three years after operation. Sixty cases were dead of internal metastases although it is not stated what organs were involved. The following table of these cases is instructive: Glands of neck and axilla negative, 5 cases; glands of the axilla positive, neck negative, 39 cases; glands of the axilla positive, neck positive, 16 cases.

This seems to show that when the glands of the axilla are involved, metastases to the internal organs take place more frequently than when both glands of the axilla and neck are involved. This is not explained by Halsted, and it is impossible to gather from his statistics any satisfactory explanation.

Greenough, Simmons, and Barney traced 376 cases out of 410 primary operations performed at the Massachusetts General Hospital. In 126 cases there was local recurrence in the scar, in 136 cases there was no recurrence. Some of their cases were operated on in the period before the removal of both pectoral muscles. They do not believe that it is necessary to dissect away the pectoralis minor. They state that metastasis to the lung was found occasionally, but they do not say in what proportion of cases. They do say, however, that the medullary breast cancer is the most malignant. The scirrhus is only slightly less so, while the adenocarcinoma is the least malignant of the three.

*W. S. Halsted, Annals of Surgery, 1907. Vol XLVI.

In my patient there were probably metastases to the brain. They could scarcely have been in the spinal cord without causing much pain and disturbance of sensation. Peabody reported a case which had pains and aches all over the body. There was no paralysis until one week before death when partial ptosis of the left eyelid, partial paralysis of the muscles of the right side of the face, weakness of the right palate muscles, and partial deafness in the right ear were discovered. There was no paralysis in the limbs or disturbance of sensation. The patient had had a cancer of the breast, which was removed four years before. At autopsy a nodule was found in the apex of the lower lobe of the left lung and in this nodule were seen several blood-vessels occluded with cancer tissue. There were no nodules in the liver but they were found in the kidneys and suprarenal bodies. There was a swelling in the cauda equina which on microscopical examination revealed cancer. Only on microscopical examination was cancer tissue found in the pia mater and in several peripheral nerves.

Effusion into the pleura that is bloody is found in only about 12 per cent. of the cases. This sort of fluid is not infrequent in tuberculosis of the pleura and in chronic nephritis. Only rarely are pieces of tissue coughed up, although there is frequently softening of the centers of the masses with actual cavity formation. A prune juice expectoration is said to be suggestive, but it occurs seldom. Emaciation is, strange to say, not marked. Persons, who at autopsy are found to have large lung cancer, do not show the cachexia so characteristic of malignant disease. The only symptoms always present are the intense dyspnea and paroxysms of cough which are out of proportion to the extent of the lesion. The air hunger reminds one of aneurysm, mediastinal tumor compressing the trachea, or of some tumor occluding the right or left bronchus. There is no pain. It seems strange that in such a massive tumor, secondary to a breast tumor, there should have been no pleural metastasis, no mediastinal metastasis, and and only surface metastasis in the right lobe of the liver. The last is remarkable in view of the fact that tumor cells were found in what was most likely a branch of the portal vein.

Judging from the cases of primary lung cancer reported, it seems quite impossible to differentiate this condition from pulmonary tuberculosis. It would likewise be difficult to diagnose secondary cancer were it not for the history of the case, for aside from the intense paroxysms of dyspnea there are no signs that enable one to say that cancer is present. Cavities may occur in cancer; bloody fluid may occur in tuberculosis. The examination of the pleural fluid is notoriously uncertain when there is question of the cancerous or noncancerous origin of a cell found in the exudate. Hemoptysis also may occur in cancer of the lung and complicate the picture. An interesting feature in this tumor is the apparent tendency to heal. This may be seen both macroscopically and microscopically.

Zinn remarked on this condition when reporting a case of chorion epithelioma which had metastasized widely through the lungs; his patient had had cyanosis, dyspnea, fever and numerous crepitant râles throughout the lungs, so that the diagnosis of acute miliary tuberculosis was made. In a review of the literature he collected 230 cases in 95 (41 per cent.) of which there were metastases to the lungs.

Cancer of the breast is generally considered cured when, after a period of three years, no metastasis has taken place. Some have lengthened this period to five or seven years. Yet when secondary cancer occurs in the mediastinum with nodules as well over the head and trunk ten years after removal of the breast for cancer, as in a case reported by McKendrick, it almost makes one hesitate to say that cancer is ever cured.

Ochsner, after reviewing the results of 98 cases, from which he had heard, says: "The review of this series of cases, although incomplete, seems to show that if the very complete operation which is now generally practised is employed in these cases reasonably early there is much reason for expecting a fair per cent. of permanent cures."

Halsted remarks that it may then be advisable in involvement of the humerus to amputate at the shoulder joint and remove much of the soft parts, and, in involvement of the trochanter of the femur, to amputate at the hip.

In summarizing the interesting features of this case, the points to be noted particularly are, in the first place, no recurrence in the scar of operation or in the tissue beneath the skin. And, although there was widespread metastasis to both lungs, there were no superficial glands enlarged except the one in the left axilla, and there were no nodules on the pleura. Moreover, the mediastinal glands were not implicated in the growth. From the standpoint of diagnosis, it would seem that the most characteristic symptom in these cases is the intense dyspnea, which comes on in paroxysms and is out of all proportion to the physical signs. Scanty sputum is also rather characteristic and occurred in this case.

Another interesting feature that it seems well to emphasize is the retention of the patient's flesh and weight, almost until the end. There was very little emaciation, quite in contrast to what one usually sees in those dying of cancer. From the objective standpoint, the failure to find in the thorax any tumor masses, the freedom of the larynx and trachea from stenosis, and the discovery of signs in the lungs pointing to emphysema and chronic bronchitis, would arouse suspicion of tumor in the lung.

PERCUSSION OF THE LUNGS.

By HUGHES DAYTON, M.D.,

NEW YORK.

INSTRUCTOR IN PHYSICAL DIAGNOSIS, CORNELL UNIVERSITY MEDICAL SCHOOL; ASSOCIATE ATTENDING PHYSICIAN, NEW YORK HOSPITAL.

Recognition of the value of symmetrical percussion of the lungs has led to its employment to the almost complete exclusion of other useful methods. In the customary directions for percussing the chest walls, great emphasis is laid upon the necessity for striking, with equal force and immediate withdrawal of the percussing finger, over corresponding points upon the two sides of the chest, in order to elicit differences of note dependent upon changes in the underlying lungs and pleuræ. Some authors go more into detail and recommend comparison of symmetrical points on the two sides down to the third rib anteriorly and percussion from above downward from this level on each side separately, on account of the asymmetry of the thoracic viscera.

So nearly universal has the acceptance of symmetrical comparative percussion of the lungs become, and so much has it been emphasized to the exclusion of other methods that only ten writers among all the authors whose works on physical diagnosis, practice of medicine, and diseases of the

lungs, published since 1896 and found on the shelves of the New York Academy of Medicine, even hint at the advisability of any other technique. Even these few writers often merely indicate the use of other methods without explanation. For instance, Sahli,[1] A. M. Corwin,[2] and G. H. Roger,[3] simply advise percussion of each chest separately from above downward as well as comparison of homologous points in the same order. Butler[4] particularly emphasizes the comparison of symmetrical points, and merely adds that subsequently any areas of dullness or hyperresonance which have been found on the front of the thorax may be more carefully mapped out. In "Interne Medicin und Kinderkrankheiten"[5] it is stated that if the note differs on the two sides, one may compare the newly heard tone with that of a selected adjacent space if the note over the latter is normal, and bearing in mind the normal regional variations.

With unilateral pulmonary lesions, comparative percussion of symmetrical points is of unquestionable value. In cases of bilateral lesions, however, such as a slight consolidation of the apices so equal in degree and extent as to yield the same note on the two sides, this lack of difference in tone may lead an observer to overlook the lesions entirely. So also in a case with distinct signs of consolidation at one apex and simple impairment of resonance at the other, the latter may be completely overshadowed by the intensity of the dullness with which it is contrasted. Symmetrical dullness at the bases of the lungs posteriorly is also not infrequently overlooked. This is recognized by F. J. Smith,[6] who speaks of the "importance of comparing the two sides of the chest for detecting mischief on one side only," and by O. Vierordt,[7] who says: "If comparison with the other side is impossible, as when both sides are diseased, one should compare with adjacent areas on the same side, bearing in mind the normal regional differences of intensity of tone." The same idea is suggested by P. Guttmann,[8] who states that if one "finds an equal, very slightly weakened note in each half of the chest, for example, above each clavicle, a determination whether this is to be considered normal or dull is difficult and at times impossible."

The frequency with which symmetrical lesions or those in the less involved lung and areas of impaired resonance adjoining actual dulness are overlooked by students has convinced me that two additional methods must nearly always be employed. After percussing the chest in the usual way, comparing homologous areas, it is fully as important to percuss each side independently in order to eliminate the chance of overlooking symmetrical variations. A still more important point is that the lung should be percussed not only from above downward, but also from below upward. The reason for this is that, with the majority of observers, the ear apparently recognizes the changes in resonance more quickly and surely in passing from a resonant to a dull note, than in the opposite order. If the percussion is not performed in this way, the tendency is to overlook an intermediate area of impaired resonance, between the normal and the dull areas, and thus to underestimate the extent of the abnormal area. Musser[9] recognizes the difficulty, but suggests no remedy. He says: "Absolute dulness is readily elicited, and all observers will usually obtain the same area of cardiac dullness. Relative dullness however, depends so much upon the method of percussion, whether light or strong, and upon the examiner's ear, that its extent will be determined differently by each observer, the personal equation being a disturbing factor." By percussing from the normal toward the less resonant area, the personal equation is partially eliminated by rendering the differentiation less difficult.

The principle of percussing toward the less resonant area holds good in percussion of the areas of cardiac, hepatic, and splenic dulness and of that due to such intrathoracic lesions as aortic aneurysm, and its application is of even greater importance in these cases, since the size of the heart, for example, is of more significance than that of an area of pulmonary consolidation. This is usually recognized, most writers advising percussion along a line running at right angles to the border of the organ to be outlined until a change of note is perceived.

The best rule of procedure in cases with complicated bilateral lesions is to percuss the chest until some portion is found which gives what may be considered a standard pulmonary resonance for the individual case, and then to percuss from this point upward and downward toward the doubtful areas. Only two works express this idea in any way, those of P. Spillman, P. Haushalter, and L. Spillman,[10] and F. O. Mayet,[11] who advise percussing always from healthy toward diseased areas.

Summary.—1. There is no fixed note corresponding with the term pulmonary resonance; but each individual chest has its own standard tone which should be determined before drawing conclusions as to the existence of pathological conditions.

2. In comparing two tones, the ear more readily recognizes a change from normal pulmonary to impaired resonance than a corresponding increase of resonance from impaired to pulmonary.

3. In simply comparing the notes over symmetrical points on the two sides of the chest, an observer may easily overlook symmetrical impairment of resonance or slight impairment on one side as contrasted with more marked dulness on the other.

4. It is, therefore, important also to percuss each lung independently, especially in cases in which one lung is obviously abnormal.

5. It is of particular value, in order to determine the limits of a pulmonary lesion, to find some portion of the lung over which the tone may be considered the standard pulmonary resonance for the individual chest, and then to percuss the chest both upward and downward from the site of such a normal resonance, so as to approach the dull areas from the normal, whether the former are at the apices or at the bases.

THE FOMITES THEORY OF DISEASE TRANSMISSION.

LESS than ten years ago it was universally held that the most common mode of the spread of yellow fever, at least of its importation into a country separated by water from an infected region, was by means of fomites—the cargoes of ships and the baggage of returning travelers. Many, indeed, were the trunkfuls of finery ruined by disinfection on the arrival of their fair owners at New Orleans or New York from some fever-infected Mexican or Central American or Cuban port—unnecessarily ruined, as we now know since the overthrow of this theory by Major Reed's convincing experiment in the little hut at Marianao. But the popular and professional belief in the infection-carrying power of inanimate objects is too firmly rooted to be shaken by disproof in the case of a single disease, and the stories of diphtheria and scarlet fever carried half way across the continent in the fur of woolly lambs and in other toys are too numerous and apparently too circumstantial to permit of denial. It gives one, therefore, something like a shock to be told by an official, upon whom rests the responsibility of safeguarding the city of New York, and in a measure the entire country, from epidemic disease, that the belief in fomites as a carrier of infection is a baseless superstition, that there are no infected cargoes, that dirty Egyptian rags may be handled with impunity, that filthy lucre is only a figure of speech and the greasy dollar can bring but contentment of mind and never disease to the happy recipient, and that infection is a purely personal matter, unrelated to clothes or books or toys or money or any article of commerce. This is not literally what Dr. Doty, the health officer of the port of New York, says in an article on the means by which infectious diseases are transmitted, in the *American Journal of the Medical Sciences* for July, but it is in substance the impression that his article conveys, and evidently that which he wishes it to convey.

While many, if not yet all, are willing to concede that the infected mosquito is the only agent in the transmission of yellow fever and of malaria, and that we can ignore fomites in the case of these diseases, it is still claimed, Doty says, that "clothing, rags, etc., constitute an active agent in the transmission of smallpox, typhus fever, measles, and scarlet fever, although there is an abundance of reliable evidence to show that this is not true." In support of his contention he recalls an experience in the autumn of 1892 when there were simultaneous outbreaks of smallpox and typhus fever in this city. At this time there were about eighty persons connected with the Bureau of Infectious Diseases of the Health Department, all of whom were brought into intimate relation with the subjects of those two diseases, some fifteen hundred all told. Although these officials went freely to and from their homes, taking no precautions in the way of wearing gowns or changing their clothing, not one of their friends or members of their families suffered from either disease. In the case of smallpox, we can hardly regard this as a convincing experiment, since it may be assumed that the families of health officials would be protected by vaccination; typhus fever also is a crowd disease, the aggregation of many individuals in badly ventilated apartments being an essential to its spread, and open air being inimical to it, as was demonstrated sixty years ago by Alonzo Clark in his shacks in the Bellevue Hospital grounds.

Doty's testimony in the case of rags is, however, more striking. His researches have failed to bring to light any cases of infectious disease in paper warehouses among the sorters of domestic or foreign rags, occurring as a result of their occupation. He also personally investigated the subject in Egypt in the rag depots at Alexandria, and says that the carefully prepared statistics of the English sanitary authorities there afforded not the shadow of evidence that the persons in contact with these rags in the sorting rooms were more prone to infectious disease than those in other pursuits. The handlers of our nasty paper money in banks and at the Treasury Department in Washington are also, he claims, no more subject to infectious disease than others who come in daily contact with much less of this stuff. In connection with this, he quotes the statement of Hilditch, of the Sheffield Bacteriological Laboratory at Yale, who says that "the bacteria present in paper money are nonvirulent, and that the forms most present are the air forms," and reaches the reassuring conclusion that "money constitutes an unimportant factor in the transmission of disease."

The practical conclusion which Doty formulates as a result of his researches and observations is that infectious diseases are usually transmitted directly from the sick to the well or by apparently healthy bacilli-carriers, or by insects. He admits, of course, the transmission of infection by the discharges from the sick, as in the case of typhoid fever and cholera, and he does not deny the possibility of infection by clothing and bedding recently in contact with the sick. But he contends that the fomites theory of the epidemic spread of disease is inconsistent with the modern theories of disease transmission, and that the control of epidemics of infectious disease consists in the detection of the sick and their prompt and thorough isolation. Applying this principle to quarantine, he would not, as a rule, submit the cargo of vessels or the clothing of well persons who have been exposed to the sick, or who have come from infected regions, to the expensive and annoying process of disinfection.

The writer's long experience as a sanitary official gives weight to his opinions so far as quarantine regulations are concerned, and one may safely accept his conclusions as regards the clothing of those who have been several days or weeks at sea since exposure to infection, but we are not ready to admit the application of his conclusions to city quarantine. He thinks it a hardship, which it undoubtedly is, and unnecessary, which is not yet proven, to detain at home those who have been exposed to infection or in whose home some infectious disease exists. The necessity for such detention, based of course on the belief that the clothing of the well may carry infection, depends largely upon the disease in question. If the disease is smallpox, there is no obligation for quarantine. The protective power of vaccination is absolute, it has been preached for practically a century, the proof of it is known to all, and those who deny it are sinners against the light. It is manifestly unjust to imprison innocent persons in order to protect those who refuse to protect themselves. In the case of scarlet fever and certain other diseases, the contagion of which is unknown and against which there is no certain means of protection except isolation, the question is different. That the contagion may reside in fomites, for a time at least, is not yet disproven, and how long infected clothing may retain its power of transmitting the disease to others is not yet determined. A physician who went directly from a scarlet fever patient to a case of confinement would be justly blamed if the parturient woman died of puerperal fever. It may be that there is no relation between the two diseases, and it may be that disease cannot in any case be conveyed through the medium of clothing or fomites. The contrary is, however, the general belief, and until it is disproved, as it has been disproved in the case of yellow fever, a member of a household where scarlet fever prevails is not a desirable person in a schoolroom. There is nothing more interesting and more indicative of progress than iconoclasm, but conservatism has its uses, and until the old theory is definitely demolished action on the new one should be very slow.

HEROES OF DEFEAT.

There used to be a pretty phrase much in favor with semi-occasional orators of the Fourth-of-July variety, to the effect that "Great are the victories of war, but greater still are the victories of peace." This bit of fine sentiment never failed to call forth a burst of applause; and, although it is now trite and rather infrequently finds its way into print, it still holds a certain ring not displeasing to the ear that does not quickly tire of good thoughts well groomed. However it may be with the victories, certain it is that the defeats of war are quite prone to outlive for many generations all remembrance of the defeats of peace. It must ever be that the positive element, the *fait accompli*, shall receive acclaim, while the negative effort, however noble, shall soon be forgotten. These abstractions come to us upon hearing that the efforts made by Major Ireland and his colleagues for the completion of the Carroll Fund have met with success. This is gratifying news, and we all have great reason to rejoice thereat. But let us suppose that Major Carroll's life had been sacrificed in vain. Let us suppose that through some blunder in technique, or other adventitious circumstance the transmission of yellow fever was still a mystery. How then would the daring pioneer, whose courageous initiative fills us with admiration, have fared at the hands of posterity?

To the unselfish devotee of science there is, of course, no thought of fame for fame's sake; but it does seem a pity that the work of so many of our ablest and most zealous investigators, whose lives of sacrifice have been spent so heroically, should so seldom hear or see any reward of their labor. Doubtless it is better to have striven and lost than never to have striven at all, yet can we always be quite sure that the particular kind of strife was quite worth while? In the case of Dr. Carroll and his associates, the experiments were successful and sufficient to prove the guilt of the mosquito as the transmitter of yellow fever; but one almost shudders to think that the outcome might have been quite otherwise because of some unprovable hypothesis or false reasoning that would have led only to defeat. Many are called to do great and helpful things for mankind, but few are really chosen to do them. The history of medical science, if written from the beginning and in full detail, would show the pathway of progress in etiological and therapeutical knowledge widely strewn with the corpses of theories and theorists long since fallen to decay and likewise forgotten. "Men live in deeds, not years;" and yet so few of their most strenuous and soul-trying efforts work out consummate good for the human race. The Jenners and the Harveys can be numbered on a very few digits, but hosts of men quite as worthy and zealous and indefatigable have tried their souls and wasted their flesh to little or no purpose in the cause of science and humanity.

No disparagement of honest endeavor need be read into this portrayal of things as they are. It simply represents a side of the matter which is seldom thought of and never dwelt upon, wisely, perhaps, and yet in the midst of our enthusiasms and celebrations of the points we are occasionally winning in the battle with disease, old age, and death, it can do no harm to remind ourselves that there are unmentioned heroes whose praises will never be sung, who have passed onward with the ever-moving caravan. Their work was trivial, perhaps, but it may have brought forth just the atom which some day will be found to satisfy the bond in the formula of some great therapeutic event, and then the hero of defeat becomes surely enough the hero of success. That should be the spirit in which every investigator, great and small, enters and leaves his laboratory in his fatiguing daily round.

Diphtheritic Septicemia.

It is the general belief among physicians that diphtheria, at least in so far as the distribution of the organism is concerned, is purely a local disease of

the mucous membranes, the constitutional symptoms being due to the absorption of toxins only. This is undoubtedly the case in the vast majority of instances, and it accounts for the curative results obtained from Behring's serum, which, being a true antitoxin, neutralizes the poison, but has little or no effect upon the life of the organism itself. That this localization is not always the case is evident, however, from the occasional instances in which the bacillus has been cultivated from the internal organs, a fact first pointed out by Loeffler in his original communication. In a few instances, also, the diphtheria bacillus has been isolated from the blood during life, usually in a mixed infection, and a few years ago Howard obtained a pure culture from vegetations on the valves of the heart. In the *Deutsche medizinische Wochenschrift* for June 24, Franze Hesse reports a case in which he obtained *B. diphtheriæ* in pure culture from the blood *in vivo*, and so was able to establish a puzzling diagnosis. A young man, previously healthy, a few days after recovery from a sore throat, so mild in character that he had not consulted a physician, was taken ill suddenly, with a fever of 104°, chills, and sweating. The throat was but slightly reddened, and on one tonsil there were a few pinhead-sized white patches. These promptly healed while the constitutional symptoms continued. The Widal reaction was negative. An injection of antistreptococcus serum was without effect. By blood culture, however, a pure strain of the diphtheria bacillus was obtained, and the diagnosis of diphtheritic septicemia was made. Two injections of 3000 units each of diphtheria antitoxin were without result. In the fifth week an endocarditis developed, and later a splenic tumor, probably due to an infarction, appeared. Pulmonary infarction, acute nephritis, and cerebral embolism caused the patient's death. This report is of especial interest, as showing that in even a mild case of pharyngeal diphtheria, the bacillus may enter the blood, and that when it does antitoxin appears to have little influence on it. Such a bacillemia may account for some of the severe cases of diphtheria which end fatally despite the early use of large quantities of antitoxin, and for those cases with profound constitutional symptoms accompanying mild local manifestations. It suggests the advisability of the more frequent making of blood cultures in cases of acute febrile attacks following mild anginas.

Desensitizing the Skin to the Roentgen and Radium Rays.

Owing to the sensitiveness of the skin to Roentgen and radium rays, and the liability to burns if they are applied for a prolonged time, the use of these two therapeutic agents has been confined chiefly to the treatment of superficial lesions. Various devices have been tried to facilitate the use of the rays for deep-seated tumors, usually with discouraging results. A new effort to overcome these difficulties, which for simplicity commends itself, is reported by Gottwald Schwarz in the *Münchener medizinische Wochenschrift* for June 15, 1909. Working on seeds he found that their sensitiveness to the *x*-ray was in direct proportion to their metabolic activity. If he exposed dry seeds to the *x*-ray even over long periods, they were not affected by it and developed into normal plants, whereas, if sprouting seeds were so treated, even for a short time, marked changes, as dwarfism and pigmentations, appeared in the resulting plants. This difference he considered to be due to the differences in metabolic activity, and drew the conclusion that if by any method the metabolism of the skin could be reduced during exposure to the *x*-rays, the effect on the skin might be diminished. The method he used to reduce the metabolism was pressure. He placed two capsules containing radium side by side on the skin, one lying loosely, the other held firmly by means of a rubber band. The difference between the resulting dermatitides was striking. Where the pressure was employed a slight blush appeared after some days, disappearing in three or four days, whereas, where there was no pressure a severe dermatitis occurred and lasted for more than a month. The same effect was produced by the *x*-ray, the rays being applied through thin blocks of wood. Where the blocks rested lightly on the skin the effects were severe and lasting; where they were submitted to pressure, slight and transient. The author concludes that the differences are due to the different metabolic activities of the free skin and of that under compression, and he believes that by pressure on the skin during radiation deep tissues may be treated without danger of superficial burns.

News of the Week.

Second International Opium Conference.—The State Department has requested all the countries which participated in the meeting of the International Opium Commission at Shanghai, China, last February to send delegates to a second conference, to be held at The Hague in the near future, at which means will be considered for the international control of the production, manufacture, and traffic in opium, with a view to the complete suppression of the use of opium except for medicinal purposes. Dr. Hamilton Wright, who was one of the American delagates to the conference at Shanghai, is preparing a programme to govern the discussion of the conference. It is hoped by the Department that the conference will also take up the question of the use of cocaine and other narcotics and habit-forming drugs. Dr. Wright is preparing legislation for submission to Congress which if enacted will place the manufacture and interstate traffic in habit-forming drugs under the supervision of the Bureau of Internal Revenue.

Child Life Exhibit.—Preparations are being made for an immense exhibit in New York City next winter, similar in scope and purpose to the recent Congestion of Population and Tuberculosis Exhibits, which will set forth the results of a widespread study of the influence of city life upon the development of children, which is to be undertaken before the exhibit opens. The mental, moral, and physical welfare of the city children will be thoroughly studied and demonstrated. The investigators will gather information about the health and education of the children, about influences of the home, the school, the churches and Sunday schools, the settlements, and the streets. Child labor will take an important place in the investigations, as will also recreation and amusement. They will also make a study of the printed matter that goes to the child. Infant mortality, the milk question, and underfeeding will be presented.

The Summer Care for Babies.—The Committee on Finance of the City Council of Chicago recently sanctioned the expenditure of $10,000 by the Department of Health for the care of infants during the summer. The city has been divided into districts, each having one or more doctors or nurses, and house to house visiting is to be carried on, the aim being to instruct mothers, and supply medical aid and actual nursing when absolutely necessary.

Low Death Rate in New York.—The lowest death rate ever recorded for the hot months in New York City was reported for the week ending July 10. It was 14.37 per thousand of population, as compared to 17.88 for the corresponding week last year. In the week in 1908 there were 1,516 deaths; this year the number dropped to 1,257. There were 303 deaths this year among infants under one year, as compared to 508 in the corresponding week last year. Seven persons died of sunstroke this year, as compared to 58 in 1908. There is also a marked decrease in infant mortality during the first six months of the present year, only 414 babies under one year of age dying of intestinal diseases during that period, while during the same period in 1908 there were 773.

Anthrax Epidemic in New York State.—A localized anthrax epidemic has appeared in Middletown, Orange County, New York. During the ten days ending July 16, forty cows, four horses, and one man died of the disease. The man died as a result of an act of bravado. Having been warned of the danger of contagion and instructed as to the necessary precautions, he placed an infected hide, which he had just skinned, around his neck. In two days the disease appeared, and the patient died in five days. The State Commissioner of Agriculture reports the epidemic to be well under control.

Pellagra in Nashville.—There are fourteen cases of pellagra among the children of the Baptist Orphanage of Nashville, Tenn. The State Board of Health has appealed to the Federal Government for an expert to aid in stamping out the epidemic.

Typhoid Fever and Malaria in Jacksonville.—The Half Million Club of Jacksonville, Florida, has issued a circular calling attention to the sanitary condition of the city. This quotes the United States Census Office mortality statistics as saying that Jacksonville ranks third "among the very large number of municipalities in which typhoid fever is continuously, or nearly continuously, prevalent with high mortality." The typhoid death rate is given as 155, per 100,000 of population. Jacksonville is also placed second in the list of highest death rates from malaria among the minor cities, with a rate of 78. In a list of total death rates the name of Jacksonville appears at the top with a rate of 28 per 1,000. The circular then states that "every resident should demand of the public authorities that every swamp, marsh, and creek of Greater Jacksonville be placed under one Health Board, and that long time bonds be issued for all sanitary improvements necessary to reduce the high local death rate to the average of civilized communities."

Russian Asylums Raided.—The St. Petersburg police recently raided five Johannite Orphanages and removed 140 children suffering from scurvy and various infectious diseases.

Coal-tar Antipyretics.—The United States Department of Agriculture has issued a bulletin prepared by Dr. L. F. Kebler, Chief of the Division of Drugs, on "The Harmful Effects of Acetanilid, Antipyrin, and Phenacetin." This gathers from medical literature, 1884 to 1907, 885 cases of poisoning by these drugs, 26 deaths, and 33 cases of habitual use. In reply to 925 letters sent to physicians asking their experience, 400 answers were received in which were recorded 814 cases of poisoning, 28 deaths, and 136 cases of habitual use.

Drinking Cups on Trains.—The State Board of Health of Kansas have had a controversy with the Board of Railroad Commissioners as to the use of the common drinking cup on trains. The Board of Health maintaining that it was a common source of contagion ordered its removal. The Board of Railroad Commissioners saying that its removal would be an impairment of the service refused to have the order carried out. The Attorney-General has recently decided the case in favor of the Board of Health.

The "Annals of Surgery" has published its July issue as a special American Surgical Association number. This makes a volume of nearly 350 pages, almost two and a half times the size of the regular issue, containing 26 articles presented at the meeting of the American Surgical Association, held at Philadelphia June 1 to 3 of this year.

Famous Typhoid Carrier.—The typhoid carrier who attracted so much attention in 1907 as the supposed cause of twenty cases of typhoid fever in seven families in which she worked as cook, and has since been confined in the Riverside Hospital, North Brothers Island, New York, recently appealed to the courts for release. In Justice Erlanger's decision refusing the petition, he said: "While the court deeply sympathizes with this unfortunate woman, it must protect the community against a recurrence of spreading the disease. Every opportunity should, however, be afforded her to establish, if she can, that she has been fully cured, and she may after further examination renew the application."

Carroll Fund.—The city of New Orleans has raised $1,800 for the Carroll Fund to pay for the house of Dr. Carroll's widow. The work of collecting was in the hands of a committee of the Orleans Parish Medical Society.

Medical Unity in Western Canada.—An effort is being made to obtain more unity in the medical requirements in Western Canada. A committee from the various provinces has been studying the situation and presented the result of their negotiations to the meeting of the British Columbia Medical Associaion at Seattle on July 22.

Catawba Sanatorium.—The new sanatorium of the State Department of Health of Virginia for the care of tuberculosis was opened on July 15. The institution is situated at the old Roanoke Red Sulphur Springs, in Roanoke County. Dr. Truman A. Parker of Richmond is in temporary charge, and will remain at Catawba until a permanent superintendent can be chosen.

New Floating Sanatorium.—The Brooklyn Bureau of Charities, a private institution, has placed in commission the old Erie ferryboat *Susquehanna* as a floating sanatorium for persons under treatment for tuberculosis. The boat is anchored in the Erie Basin. Miss Mary Harriman, daugh-

ter of E. H. Harriman, contributed part of the funds for fitting up the boat, the remainder having been raised by a sale of Red Cross stamps at Christmas time.

Sunnyside Association to Incorporate.—Application has been made to the Supreme Court of New York for the incorporation of the Sunnyside Association, the object being to establish and maintain a Summer home and to provide for Summer outings for children and mothers.

Babies' Dispensary for South Bend, Ind.—The Children's Dispensary Association of South Bend, Ind., has opened a new dispensary for the care of sick babies. Milk and medicines are distributed free to those who cannot afford to pay. Dr. C. E. Hansel is in charge.

New Building for Canadian Hospital.—Work has begun on the erection of new buildings in connection with the Western Hospital of Toronto, Canada, to cost in the neighborhood of $75,000. All the buildings will be absolutely fireproof and modern in every respect. The largest building is a pavilion 126 feet in length, with a verandah of twelve feet.

Hospital Moved.—The National Railroad Hospital of Laredo, Texas, has been moved to Monterey.

Huron Street Hospital Reopened.—The Homeopathic Hospital situated on Huron street in Cleveland, Ohio, has reopened after being closed for a year. An effort to change the name of the institution and admit physicians of the regular school to the staff has so far been prevented by the courts. The case has been appealed to the Circuit Court. The officers of the new staff under which the hospital reopened are: *President*, Dr. Harland Pomeroy; *Vice-President*, Dr. H. L. Frost; *Secretary*, Dr. C. S. Cutter.

Hospital Bequests.—The Eleanor Moore Hospital of Boone, Iowa, has received a bequest of $3,000 from Mrs. Mary Burwell, and the Mayville Hospital of Mayville, Ky., $1,000 from Mrs. Mary V. Wilson.

Insane Asylum to be Abandoned.—The hospital for the insane in South Orange Avenue, Newark, N. J., owing to overcrowding and lack of space for additions, is to be abandoned shortly and its 700 patients removed to the Overbrook Asylum, near Caldwell, N. J.

The American Hospital Association has issued a preliminary program for its eleventh annual conference, to be held at the New Willard Hotel, Washington, D. C., September 21 to 24, 1909. The program at present contains, besides the address of welcome and the President's address, eighteen articles and reports. The feature of the conference is to be the report of the Special Training School Committee, which will recommend curricula apparently suited to the needs of the different classes of hospitals, and make various other recommendations of importance to training schools. Copies of this report will be distributed to the members of the Association about two weeks prior to the meeting.

Wisconsin State Medical Board.—The following physicians have been appointed members of the board: Dr. John M. Beffel of Milwaukee, Dr. W. L. Thompson of Sheboygan, Dr. C. W. Rodecker of Wonewoc, and Dr. H. A. Brandt of Milwaukee.

New Hospital for Chicago.—The Board of Directors of the Norwegian Lutheran Deaconess' Home met recently and completed arrangements for a new $75,000 hospital, which is to be built adjoining the old Home at Haddon Avenue and Leavitt Street. The architect submitted the plans for the building, and they were accepted.

Obituary Notes.—Dr. R. C. Reed of Los Angeles died at the home of his son, at Stockton, Ohio, on July 1, 1909, aged 84 years. Dr. Reed was a graduate of the College of Medicine and Surgery of Cincinnati, in the class of 1860. For twenty-five years he held a professorship in this school, and for many years was the dean. He was a member of the Butler County Medical Society, the Ohio State, and the American Medical associations. He retired from active practice twenty years ago, and since then he has lived in Los Angeles.

Dr. William H. Powers of Ocala, Fla., died at his home on July 4, aged 33 years. He was graduated from the Medical Department of Vanderbilt University in 1900. Dr. Powers was a member of the Marion County Medical Society and the Florida State Medical Association. He was considered one of the leading young physicians in that part of Florida.

Dr. Edward Z. Cole of Baltimore died at his home on June 29, 1909, of heart disease following heat exhaustion, aged 55 years. He was a graduate of the Hahnemann Medical College of Chicago. Dr. Cole was the founder and president of St. Luke's Hospital in Baltimore, professor of gynecology of the Atlantic Medical College, and a member of the Institute of Homeopathy, and many other societies.

Dr. Frederick Richard Loeber of New Orleans died at his home July 1, 1909. He was a graduate of the Medical Department of Tulane University in 1899, and a member of Orleans Parish Medical Society, and the Louisiana State and American Medical associations.

Dr. Edwin H. Van Dusen of Kalamazoo, Mich., died on July 9, at his home, at the age of 81 years. He was a graduate of the College of Physicians and Surgeons of New York in 1851. Dr. Van Dusen was for thirty years the superintendent of the State Insane Asylum at Kalamazoo. He was also well known for his philanthropic work.

Obituary.

EDGAR HOLDEN, M.D.

NEWARK, N. J.

Dr. Edgar Holden of Newark, N. J., medical director of the Mutual Benefit Life Insurance Company, and President of the Association of Medical Directors of Life Insurance Companies, died Sunday night at his summer home, Chatham, N. J., from angina pectoris. Dr. Holden was born at Hingham, Mass., November 3, 1838, and was graduated from Princeton College in 1859. He received his medical degree from the College of Physicians and Surgeons in this city in 1861, and entered the United States Navy in the autumn of that year, serving throughout the Civil War. Dr. Holden was a member of the New Jersey State Medical Society, of the American Laryngological Society, the Essex County Medical Society, the Newark Medical and Surgical Society, the New Jersey Academy of Medicine, and the New Jersey Microscopical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

EFFUSION INTO THE BOWEL-WALL—RED DEGENERATION OF FIBROIDS—TYPHOID CARRIERS—HUNTERIAN MUSEUM—R. C. S. ELECTION—CAVENDISH LECTURE—INSPECTION OF SCHOOL CHILDREN—TUBERCULOSIS EXHIBITION—LORD STRATHCONA AND THE MEDICAL FACULTY—A HOSPITAL CARNIVAL—OBITUARY.

London, July 2, 1909.

At the last meeting of the Medical Section (R.S.M.) Dr. Sutherland explained at considerable length his views on gastrointestinal crises determined by effusion into the bowel wall and criticised the diagnosis of a number of recorded cases. Not that he assumed any superior diagnostic insight, for he modestly said he had apparently made more mistakes than any one, and put that forward as his only claim to discuss the subject. It is certainly refreshing to meet such readiness to admit errors. Henoch's purpura is the type of disease of which he treated, differing only from other forms of purpura hæmorrhagica by severe abdominal symptoms —pain, vomiting, and passage of blood and mucus, often simulating intussusception, which may be associated with it. Hemorrhages into the bowel wall have been found during life on operation, and also after death at post mortem, and explain the clinical symptoms. The ileocecal region was the site of election, but the lower end of the ileum, the cecum, more rarely the appendix, may also be affected. It should be remembered, too, that over 70 per cent. of cases of intussusception in infants occur in the ileocecal region. The diagnosis between this and effusion is almost impossible. Dr. Sutherland did not pretend from study of recorded cases to find one point to distinguish them. Invagination may, in fact, be either an early or a late complication. Some of the cases he related prove this important point, and should suggest the danger of overlooking its probability. It seems easy to understand why this should be and why intussusception should have been considered as sometimes terminating in spontaneous reduction. Dr. Sutherland once accepted this occurrence, but now hesitates to admit it. So cases described as chronic or recurrent intussusception might just as well be explained as due simply to effusion into the bowel wall, which may also simulate the several forms of colitis. In the discussion that followed this interesting paper Mr. Arthur Edmunds showed colored pictures and drawings illustrating the case of a boy, aged 3, who had a sudden attack of acute pain, vomiting, and an indefinite swelling. Intussusception was diagnosed, and on operating the appendix was seen to be hemorrhagic and amputated—no intussusception. The wall of the appendix was infiltrated with blood. Mr. Edmunds further showed that in spontaneous recovery from intussusception its site was marked by a pale, edematous area. Mr. Hugh Lett said he was chiefly guided as to operation by the presence or absence of a tumor which, he found, could be felt in most cases of intussusception. In reply, Dr. Sutherland remarked that the edematous area described by Mr. Edmunds might serve to differentiate hemorrhage into the wall from intussusception, and in reference to the presence of a tumor Mr. Lett put its incidence higher than most teachers; but perhaps that was due to his method of examination.

At the Obstetrical Section of the Royal Society of Medicine on the 10th inst. Mr. Bland Sutton read notes on a case of red degeneration of a uterine fibroid associated with *Staphylococcus pyogenes aureus* in a primagravida of two months, who was seized suddenly with severe abdominal pain. Twenty-four hours later operation was performed, when a large subserous fibroid was found and several interstitial ones. Hysterectomy was done and the tumors examined by Mr. Somerville Hastings. The larger had an area of softening covered with lymph. From this "infarcted area" a pure culture was obtained of *Staphylococcus pyogenes aureus*. Interstitial fibroids showed the red change in streaks, but no microorganisms. This subject has also been before the Dublin Academy of Medicine, at which the president (Dr. Tweedy) exhibited specimens removed six weeks after delivery which had been induced at full term. There was high pulse and temperature on the third day, increasing to 103° next day; but it subsided and the patient recovered. The tumor was removed by supravaginal hysterectomy. It showed in a very characteristic manner red degeneration, or disease, Dr. Tweedy remarked, very rarely occurring except in pregnancy. High temperature was a constant symptom, and this, he thought, might be due to absorption of toxic matters from the degenerating myoma. In the discussion that followed Dr. Purefoy said he was not quite sure that the high temperature was due to the red degeneration. There might be some localized sepsis. Dr. Jellett was watching a patient, six months pregnant, with a large myoma below the fetus, filling up the pelvis. He asked how Dr. Tweedy would deal with it. Dr. Rowlette mentioned the points about red degeneration which may be regarded as fixed; it was associated with pregnancy, seldom other conditions; it was found in almost every myoma associated with pregnancy; it was a necrotic change, as the tissue did not stain; in the highly vascular state of the pregnant uterus anything interfering with the blood supply and causing stasis in the veins might give rise to diffusion of blood pigment; it might produce high temperature through being invaded by septic or putrefactive organisms. In reply, Dr. Tweedy expressed the opinion that there was a toxin which could raise the temperature apart from an invasion of germs. In his case it was only when he felt convinced that the growth had undergone degeneration that he determined not to let her run the risk of another pregnancy. Dr. Jellett's case he thought plain sailing; he should not allow labor to set in, but calculate full term and do a cesarean section. After removing the child it would be easy to do hysterectomy. The myoma would certainly degenerate if the patient were permitted to fall into labor.

A memorandum has been issued from the War Office by the Director-General of the Medical Service on "chronic carriers" of typhoid. It states that Kayser collected 101 cases of cured typhoid which were said to be free from bacilli. Two years after convalescence three of them were found to be carriers. Recent work is confirmatory, and it may be considered as established that 3 to 4 per cent. of convalescents from enteric fever become chronic carriers and that in the neighborhood of enteric fever cases a small percentage of the community may be temporary harborers of the bacillus. The idea of treating carriers with lactic acid has been tried in two intestinal cases with apparent success. Other patients were treated in groups by anti-typhoid vaccination. At first the vaccine prepared in the Royal Academy Medical College was used. This had proved a very effective prophylactic; but for treatment though it increased the protective substances in the patients, it did not arrest the bacilli. It is suggested that races of bacilli may vary in their resistance to protectives, and if the best results are to be obtained the Director-General says vaccines from the infecting bacilli must always be employed. Instead of a general vaccine auto-vaccines are now generally being used, through which it is hoped the bacilli may be got rid of.

Yesterday at the Royal College of Surgeons the additions, 383 in number, made to the Hunterian Museum during the year were placed on view and will remain until to-morrow night. The collection of specimens of the Odontological Section of the Royal Medical Society has also been offered and accepted by the college. It numbers some 5,000, and when they have been transferred this department of the museum will be one of the most complete in the world; for the collection it will enrich was already extensive and valuable, containing as it did many specimens used by Hunter in his work on the teeth. The conservator of the Hunterian Museum, Professor Keith, has adopted a new form of card catalogue in specially designed boxes attached to each case of exhibits so that the visitor finds at hand a history and explanation of each specimen. There was an additional reason for choosing yesterday for a visit, as the election of three fellows to the council took place in the afternoon. The poll was a record one, 971 votes being given. In the result Sir Watson Cheyne and Mr. Clement Lucas were re-elected and Mr. Harrison Cripps was elected.

Sir Victor Horsley delivered the Cavendish lecture at the West London Medical Clinical Society, taking for his subject the cerebellum as the organ of automatic actions, such as walking, running, and standing. Newly born animals could not stand because the cerebellum was not fully developed at birth. But a great deal of muscular control was dependent on the spinal cord. The spinal centers also as proved by experi-

ments do a good deal of what are called voluntary acts. We walk on four limbs, the arms moving alternately with the legs, and running is an extreme instance of this. Information was provided for the purpose of movement by the semicircular canals, and when they become diseased the head and body take attitudes which serve as aids to diagnosis. Sir Victor illustrated his lecture by views of the cerebellum, photographs of people running, and portraits of ear diseases. After the lecture a concert was given and various medical and surgical exhibits were on view.

At the Institute of Hygiene a resolution has been passed calling on the Board of Education to prepare a plan upon which all statistics referring to the medical inspection of school children should be so tabulated as to render the results of various districts strictly comparable. It was also agreed to ask that serious defects revealed by inspection should be promptly attended to and due remuneration secured to medical practitioners doing the work. Further, that fees should be recovered from parents, and the opinion was expressed that in the first instance existing institutions should be utilized for children whose parents were unable to pay for private attendance.

The Tuberculosis Exhibition has so far proved very successful. Some 50,000 to 60,000 persons of the poorer class have visited it and evinced much interest in it. A conference of public health authorities from all parts occupied three days. It is now proposed to transfer the exhibition to other poor districts of London and subsequently to industrial centers in the provinces. In this way it may become a traveling school of hygiene for the people—in fact, an anti-tuberculosis mission.

Of course you learn this morning, as we do on this side, of Lord Strathcona's renewed munificence to McGill University, and will be as pleased as I confess to be that this time it is the medical faculty which is to be so richly endowed. You will remember that his concern for medical science was formerly evinced by founding the chairs of pathology and of hygiene at McGill. The new gift of £100,000 to the medical faculty is indeed a noble one.

King's College Hospital, as you know, is to be removed to the south side of the Thames, but it will probably take a couple of years yet to effect the transfer. The cost is estimated at £300,000, of which about £225,000 has been promised. To raise the remainder a great carnival, under the patronage of the Prince and Princess of Wales was held yesterday at the Crystal Palace. It was unique among charity fêtes, and the promoters aimed at making it the biggest and cheapest. There was a bewildering list of entertainments, most of them free, but a few cost visitors the extravagant fee of 3 or even 6 pence. There was a huge company, and the fête continues to-day in much finer weather. A great addition to the fund is assured.

Dr. Thomas W. Bridge, Mason Professor of Comparative Anatomy and Zoology in the University of Birmingham, formerly at Cambridge and Dublin, died on Wednesday at the age of 60. He contributed many papers to the subject of his professorship.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE MANNER OF DEVELOPMENT OF CHOLERA EPIDEMICS—PHILIPPINE MEDICAL SCHOOL—APPROPRIATION FOR THE BOARD OF HEALTH—SOCIETY FOR THE PROTECTION OF INFANTS—A NEW PHARMACY LAW—WORK OF THE HOOKWORM COMMISSION—PERSONALS.

MANILA, P. I., June 6, 1909.

CONSIDERABLE uneasiness was injected into the local cholera situation last week by the appearance within a period of two days of four deaths in persons who suffered with many of the clinical symptoms of cholera. Careful laboratory investigations made of the intestinal contents, both *ante-mortem* and *post-mortem*, however, failed to reveal any cholera organisms.

It will perhaps be remembered that the carefully recorded experience since 1905 shows that in the four outbreaks which have occurred since that time, deaths have first occurred among persons who had many of the clinical symptoms of cholera, and that true Asiatic cholera follows in from four to six months after the first of such cases. The earlier deaths show many of the clinical symptoms of the disease, but no cholera organisms can be found. These are followed by other cases at intervals of a few weeks which resemble more and more the clinical picture of cholera, and finally curved organisms which are slightly motile and grow near the bottom of the media are found in the stools. Clinically, such cases give a history of sudden onset with vomiting which lasts for a period of six to twenty hours, marked diarrhea with stools not typical of cholera, extreme collapse, severe cramps in the arms and legs, profuse sweats, subnormal temperature, rapid pulse, anuria, and other evidences of intense intoxication, for which active stimulation, external heat, hypodermoclysis, intravenous transfusion of salt solution, or serum are of no avail. On *post-mortem* these cases show marked rigor; dryness of the abdominal cavity; intestinal contents not typical of cholera; the ileum and large intestine are studded with small, beadlike elevations; evidences of intense acute nephritis and punctiform hemorrhages upon the serous surfaces of the heart, and cultures made by competent observers fail to reveal cholera organisms. However, each succeeding case gradually approaches more and more the findings of cholera, both clinically and at autopsy, until finally the autopsies are typical and the cholera organism is recovered from cultures taken from the intestines.

The Philippine Medical School will commence its third annual session on June 7 with a freshmen class of 27 students. The entrance requirements compare favorably with those of the better medical schools of the United States, and it is therefore most encouraging to note that the educational facilities in the islands have become such that the Filipino students may secure the necessary preliminary education successfully to pass the entrance requirements of the Medical School.

The Philippine Legislature, which has just adjourned, has again made substantial appropriation for the routine work of the Bureau of Health, and, in addition, has appropriated a sufficient sum to enable the bureau to commence an active tuberculosis campaign. It is proposed to do this by opening a tuberculosis dispensary in the city of Manila, with a trained nurse on duty at the dispensary and another trained nurse to visit the patients in their homes, all, of course, to be under the direction of competent medical men. It is also proposed to start a night camp on one of the elevated sites near Manila, where popular lectures on tuberculosis and practical instruction will be given, the latter to be on sleeping, eating, disposal of sputum, etc. Those who are actually afflicted with the disease will be provided with sleeping quarters for periods of several weeks, and it is hoped that when they return to their homes they will continue the régime taught at the night camp. It is believed that in this way a large number of people can permanently be benefited. For the actual treatment of incipient cases it is proposed to construct a number of individual shacks in the mountains of Benguet in order to ascertain whether the cool atmosphere and the elevation of that region can be counted upon to be of material aid in the treatment of tuberculosis in the Philippines.

The Philippine Legislature also made an appropriation of $5,000, which is to be used by the Bureau of Health principally in aiding in the support of the Society for the Protection of Infants, the object in view being to make a substantial effort to reduce the infant mortality in the City of Manila by a system of education and the distribution of wholesome milk.

The Legislature has also passed an amendment of the Pharmacy Act, which might well commend itself to similar legislative bodies in the United States. It provides: "That * * * it shall likewise be unlawful to compound or dispense physicians' or veterinarians' prescriptions, recipes, or formulas which are written in cipher, or in which there are employed unusual names of drugs which differ from the names ordinarily used for such drugs in standard pharmacopœias or formularies. Any person violating this provision shall be punished by a fine of not more than $500, and in case of a recurrence of the offense the Board of Examiners may, upon conviction of the offender, revoke his certificate of registration in accordance with the provisions of section 14 of this act."

The Hookworm Commission, of which mention has previously been made, and which has been studying this problem at Taytay, has discontinued further work for the present on account of the fact that the majority of its members were either connected with the Philippine Medical School or were students therein, and as the school is again about to be opened the work will necessarily have to be delayed until the next vacation

period. However, the hookworm work in the islands is not to stop on this account. The Bureau of Health is putting a commission of its own into the field, which will shortly commence operations at the town of Las Piñas, in Cavite Province.

Dr. E. Martini of the German Naval Service, who has been on special detail at the Bureau of Science for the purpose of studying blood parasites of animals, has returned to his station at Tsing Tau, China. He expects to return in the near future and continue his researches.

Dr. W. J. Lindley, who was formerly the quarantine officer at Savannah, Ga., has been transferred to Manila, and is now on duty here.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 8, 1909.

The Widening Sphere of Medicine.—In an elaborate address by E. W. Taylor, the author says that in the feverish anxiety to train men adequately for certain well defined and essential branches of medical work, the broader possibilities of medical education have been strangely overlooked. The standard has been raised to advantage, and must not be lowered in the slightest degree, but it must be broadened and the attempt must cease to turn all medical students out of the same mold. Under no circumstances should men of unquestioned capacity be excluded from our medical schools because they may fail to conform to a preconceived standard. The pendulum has swung far in the direction of so-called scientific research with only good results, and the very success of such a movement is likely to develop intolerance, and the intolerance of the man of science is peculiarly difficult to meet. There is danger that at times we lose sight of the utilitarian function of the medical school. Its service is ultimately practical, whatever may be the means to that end. In the pursuance of this object there are strong indications that the system which has given free choice of studies through four years of academic life and four years of rigid requirement through the medical school will become reversed or at least modified. We must have an elective system in the medical school. There is no need of requiring obstetrics of one who is to become a bacteriologist, or a course of surgery of one who will be an internist. To accomplish our ideals, our medical schools must adopt a broad as well as a high standard, and must clearly recognize the fact that in the future, medicine will unquestionably offer fields of usefulness and honor to many men seemingly unfit if judged by the present narrow requirements.

The Pharmacopeia: What It Is and What It Is Not.—S. Solis-Cohen says that, first of all, the pharmacopeia is not a work on therapeutics. Its function is neither to explain the action nor to define the uses of remedies; neither to affirm nor to deny the opinions and conclusions of pharmacologists and clinicians on these; neither to recommend or deprecate the use of any agent or preparation which physicians may require at the hands of the pharmacist. The pharmacopeia is a book of processes and standards, giving directions for the making of certain medicines, and giving, in addition for all, drugs, prescriptions, and tests by which they may be recognized, and their identity, purity, quality, and strength be determined. It is this, and nothing more. Evidently its scope must be comprehensive. It should formally exclude nothing which the physician is apt to call upon the druggist to furnish the patient. Routine mixtures should not be included, except a few such as paregoric, tincture of cardamom, etc. and a few like Dover's powder and Basham's mixture. We have a full list of all mixtures in the book known as the National Formulary. There should be nothing of a secret nature in the pharmacopeia. At the next revision there should be appointed a committee on international nomenclature. If new products are introduced without previous submission to the committee on nomenclature, and these remedies become of sufficient importance in practical medicine, the committee should select an appropriate name for the new remedy and the insertion of this name in the pharmacopeia will give the new remedy an official standing. Manufacturers would soon find it to their advantage to cooperate with the committee in all these matters.

New York Medical Journal, July 10, 1909.

Prognosis in Eye Diseases Viewed from the Standpoint of the Patient's Rights and the Ophthalmologist's Duty.—A. Duane says that it is rarely justifiable to tell the patient that he cannot recover, and that nothing can be done for him. The conditions in which this sort of statement is oftenest made are: (1) Extensive disease of the cornea; dense corneal opacities, staphyloma, keratoconus; (2) iridocyclitis; degenerative iridochoroiditis, and other degenerative or destructive affections of the uveal tract; (3) retinitis pigmentosa; (4) optic nerve atrophy (including high-grade toxic amblyopia); (5) glaucoma; (6) progressive high myopia; (7) detachment of the retina; (8) intraocular hemorrhage; (9) cataract; (10) injuries, including operations. A series of clinical histories is given, showing how proper and persistent treatment may bring about happy results under the most unpromising circumstances. These histories justify, in the author's mind, the following propositions: (1) An error in prognosis is often more disastrous to the patient and more humiliating to the surgeon than an error in diagnosis or in treatment; (2) be the condition ever so desperate, we are rarely justified in admitting even to ourselves that the case is hopeless and that nothing more can be done; to make such a statement to the patient, except in the very rarest instances, is needless and often very pernicious cruelty. This is so because (a) our diagnosis and prognosis are necessarily fallible; (b) even if the diagnosis is accurate and the prognosis apparently so according to present standards, we never know how soon some new discovery may change our views of the one or the other; (3) brutal positiveness, often regarded as an evidence of honesty, is more frequently a sign of sheer selfish inconsiderateness on the part of the surgeon, who will not take the time or trouble to mitigate the blow he is inflicting nor give the patient the explanations necessary to qualify his downright assertions. Sometimes such positiveness is simply a mark of ignorance; the expression of a hastily formed and erroneous opinion; (4) if we maintain a cheerful and determined optimism we not only help the patient to bear his troubles, and by giving him hope prevent much suffering and mischief, but we are ourselves stimulated to make greater exertions in his behalf and are prevented from degenerating to the dead level of routine treatment or to the depths of an actual therapeutic nihilism; (5) in pursuance of this optimism, we should strive to emphasize the favorable points of the patient's case, call attention to the fact that he is holding his own, attend with sympathy and patience to his complainings, and lay stress on any factors in his case that we can ameliorate; (6) even when there is nothing much we can do, the patient often derives encouragement and satisfaction from the sympathetic cheerfulness that we have the power to give him when he visits us; (7) there are some cases, of course, in which optimism would be wrong. There are patients who have to be handled without gloves, and who have to be frightened or dragooned into obedience. In such cases brutal frankness is necessary, provided always that by it we can secure some good to the patient.

The Surgical Appendix.—R. F. Ward groups the appendix cases as: (1) Acute infective; (2) obliterative, that is, involution of the appendix, fibroid appendix, and (3) secondary. He presents the salient features of each form of disease, and indicates the mode of procedure to be followed. Under the first heading nothing new is presented, the author simply detailing his own technic and giving his reason therefor. The second form, chronic nonsuppurative inflammation of the organs, he regards as the most common. The normal structures give way to a formation of hyperplastic connective tissue which gradually in time replaces nearly all of the original structures. The irritation caused by the pressure of the contracting connective tissue around the sensory nerve filaments is the cause of pain over the appendix and in this region. Through the sympathetic fibers which are caught are produced all manner of reflex disturbances affecting the gastrointestinal tract. These vary from the slightest intestinal dyspepsia, to the most obstinate intestinal derangements of secretion and excretion. These cases are to be treated in the same way as are the "interval" cases. The third form is most frequently found in connection with a right salpingitis, salpingo-oöphoritis, acute or chronic oöphoritis, or a tuberculous peritonitis. A direct involvement, causing concomitant surgical appendix, or adhesions and constricting bands, interfering with the blood and lymph supply, may cause subsequent inflammation of the appendix, of the acute suppurative or obliterative type. Whenever the abdomen is opened for the relief of an inflammatory process in the neighborhood of this organ, it should be removed whether it appears to have shared in the inflammatory process or not. When lymph is present on the peritoneum, it should not be removed, as it signifies the presence and activity of the phagocytes, which are capable of destroying the infective matter, with two exceptions, (1) overwhelm-

ing virulent organisms; and (2) subnormal production of phagocytes, from any cause. The appendix can be removed without hesitancy where there is production of lymph from an inflammation of an adjacent organ, while judgment must be exercised in its removal at the same time that other intraabdominal operations are being done for noninflammatory or quiescent conditions.

Agricultural Aspects of the Pellagra Problem in the United States.—C. L. Alsberg says that pellagra is caused by the consumption of Indian corn, that is, spoiled corn consumed by poorly nourished and badly housed individuals. The tendency of the farmer is to harvest his corn before it is fully ripe, and this promotes the tendency to disease in the grain. Moreover, a most important factor is the present faulty method of transportation in bulk. The grain of corn is a live thing. It breathes, consumes oxygen, and gives off CO_2 and heat. The latter increases sufficiently to create ideal conditions of temperature and moisture for the growth of fungi. Corn shipped to the Northeast will have the tendency to ferment checked by the colder climate; if sent South the reverse effect follows. The avoidance of moisture in bulk transit is the thing desired. It is to the interest of the farmer to sell corn with as great a moisture content as possible, for such corn is heavy and will average more bushels to the acre than after proper drying and curing. When it is loaded into cars it straightway heats up, ferments, and spoils, often before it reaches its destination. The dealer who receives such corn naturally often succumbs to the temptation of mixing it with enough good corn so that meal made from the mixture will not be offensive to the taste or smell. The amount of spoiled corn used in this way is very great. The only rational means to combat this evil is to induce purchasers of corn to pay for it according to its moisture content. The remedy in its last analysis is therefore to cause the corn to be thoroughly dried before transportation.

Journal of the American Medical Association, July 10, 1909.

Preventable Deafness.—W. Sohier Bryant says that all deafness is preventable and its study involves consideration of all otology except that part dealing with equilibrium. The middle-ear changes causing deafness can be placed in two pathologic groups: (1) Ulcerative, necrotic, hypertrophic, adhesive, and cicatricial processes; (2) atrophic and selerosing processes. The two fundamental etiologic factors of these are infection and toxic vasomotor paresis, usually of infectious origin. That is, all forms and almost all cases of middle-ear deafness are the results of infection. This is clear enough in suppurative cases, but in cases of progressive deafness it is not so apparent, though inspection of the nasopharynx will reveal it. The prevention of infection, therefore, by keeping the mucous membrane normal, raising the local resistance, and destroying infectious organisms by strict attention to the hygiene, is the method of cure. Local hygiene requires attention to a great variety of detail—removal of obstructions to respiration, both because they obstruct and on account of their evil reflex effects and their hindrance of proper drainage—and attention to their causal factors is one of the essentials. Infections of the nasopharynx also require special attention, especially those which are not easily apparent and do not suppurate. They usually occur on the posterior superior wall of the pharynx. Orthopedics of the facial bones and teeth are also important factors. It is needless to say that pure air and hygiene are also important. The second group of changes causing middle-air deafness are the atrophic and sclerosing processes, which are also dependent on infection as already described, or by having induced a toxic paresis of the sympathetic nervous system, as occurs in abnormal mental conditions, shock, fatigue, etc., affecting the bodily functions in neurasthenic states, menstrual and obstetric abnormal conditions, etc. The hereditary tendency to those conditions is not real but only apparent. The unstable nervous system, the weak digestion, and the unbalanced metabolic functions are inherited, but the exciting cause of the diseased hearing is lacking unless some additional stress throws these weak functions out of balance and gives the initial stimulus to the condition of toxic paresis of the sympathetic system, causing the middle-ear deafness. The success in preventing deafness from middle-ear disease is in proportion to the rapidity of cure of the middle-ear infection. The acute inflammatory conditions require energetic measures for drainage and preservation of the middle ear structure, and, in convalescence from acute inflammation, inflation should be practiced in order to prevent contractions and adhesions and to keep the hearing apparatus in its proper place. Syphilitic middle-ear diseases respond readily to specific treatment. Periodic examination of patients is important for success. This is true in all cases of deafness, but especially so to prevent the insidious deafness due to middle-ear atrophy and sclerosis. If the patient waits until he is already deaf, he will bring to the specialist a very resistant sound conduction disease. The author's summary is given as follows: "Practically all deafness is due to the results of infection. Causes leading to infection are to be corrected, the soil is to be rendered non-retentive, and the existing ear defects are to be treated at once. Avoidance of the infectious organisms, the maintenance of the nasopharynx in a healthy condition, the eradication of any existing infection, and the avoidance of impairment of the sympathetic nervous system, through toxic action of fatigue or infection, will insure against deafness. To insure immunity from deafness, it is necessary for the individual to undergo a periodical otorhinopharyngeal examination perhaps once a year, so that any incipient middle-ear disturbance may be detected and corrected before the condition has become established."

The Visual Fields in Hysteria.—From a clinical study of 50 cases, W. R. Parker questions the commonly made statement that a concentrically contracted field of vision is the most common ocular stigma of hysteria. The cases are not selected ones, and are all observed under like conditions. He sums up his conclusions substantially as follows: (1) Dyschromatopsia is more common than concentrically contracted fields in the ratio of 72 to 40; (2) there is no relation between the contraction of the visual fields and amblyopia, the former being present in 96 per cent., while the latter was present in 8 per cent. of the cases; (3) there is no constant relation also between the areas of anesthesia and concentrically contracted fields. Of the patients with anesthesia 28.4 per cent. showed concentrically contracted fields, while 75 per cent. showed dyschromatopsia. In a note appended he states that not a single case of hysterical hemianopsia has been recorded in either the ophthalmologic or neurologic clinics of the University of Michigan.

Food Intoxications in Children.—J. Ruhräh describes the dietetic disorders in children which constitute a considerable proportion of the cases which we are called on to treat. Leaving out the chronic gastric and intestinal disturbances, there are a large number that are due to overfeeding. These may be caused by too much food of all kinds and too little exercise, or by too much fat, protein, or carbohydrate, or too much of any combination of these. There are, also, individual idiosyncracies of children to any one of these, and it is well to remember also that disease of some organ may in a reflex way upset digestion or metabolism. We cannot make a symptom-complex of each of these conditions, though it is to be hoped that it may be possible in the future. The most suggestive thing is a train of symptoms occurring periodically, no matter in what combination. The next step in diagnosis is by careful physical examination to exclude any disease of any organ and then to study the child's habits as to food. Sometimes the fault is easily found. In other cases it requires careful investigation, and sometimes trial diets. The following points are of use: Taking too much food of all kinds usually causes what are ordinarily known as bilious attacks, with recurring fever, coated tongue, foul breath, headache, malaise, often drowsiness; there is often vomiting or diarrhea, and the liver may be enlarged and tender. A brisk purge and a limited diet is usually all that is needed. Too much protein causes, as a rule, much the same symptoms, sometimes one and sometimes another of the above symptoms being the most prominent. There may be acute indigestion or simply furred tongue and foul breath. Cases due to too much fat are characterized by attacks when the child is not well and has a pale, muddy skin, and large dark circles under the eyes; a coated tongue and exceedingly fetid breath are one of the most striking features. There may be gastric disturbance and vomiting, and often diarrhea with undigested fat in the stools. The carbohydrate cases are the most numerous of all, owing to the indulgence of children in sweets. Many children have a very low capacity for utilizing sugar. The recurrence periodicity is, as in the other cases, most characteristic. Perhaps the most common form of attack is recurrent vomiting, though this occurs also in protein disturbances. In some cases the attack consists merely of fever and sick headache, while in others there are attacks of asthma following indiscretions in diet. The most difficult cases are those in which there is a combination, such as an inability to utilize normal quantities of protein and carbohydrate, making it difficult to arrange the diet satisfactorily. If the cooperation of the family can be secured, after determining the food factor at fault, the results are remarkable. An effort should be made to determine just

what quantity of the disturbing factor can be borne, and then keep the child on a diet well within the limits of its assimilation. In addition, the bowels must be kept regular, and it is well to use an active purge at least once a week. Outdoor life and plenty of exercise are exceedingly important.

Reflex Aural Neuroses from Eyestrain.—S. Theobold notes the slight attention that has been given to the effects of eyestrain in producing reflex ear troubles. He has not been able to find any mention of these in the Index Catalog of the Surgeon-General's library. While tinnitus is the aural reflex he has most frequently encountered as the result of eyestrain, it is not the only one. Others that may be mentioned are, a "muffled" or "stuffed" sensation in the ear, pain, not severe, and as often felt around and in front of, as in the ear; impairment of hearing which, according to the tuning fork indication, was due to disturbance of the perceptive rather than of the conducting apparatus. Whether the vertigo recognized as a symptom of eyestrain deserves to be called an aural reflex, he is unable to say, but he thinks the derangement causing it may be located in the semicircular canals. Of tinnitus due to eyestrain, he has observed three distinct varieties—the more usual or vascular type, the relatively low pitched, whirling or fluttering sound caused by irregular contractions of the tensor tympani, and the high-pitched, almost musical, intermittent tinkling produced by like contractions of the stapedius muscle. The evidence in favor of the ocular origin of the aural sensations mentioned is in their disappearance after the relief of the eyestrain, their greater intensity when the eyestrain is most troublesome or their appearance or aggravation by use of the eyes. The ocular fault often present was astigmatism, sometimes of high degree and associated with other refractive errors, though, in some cases, it was chiefly heterophoric. The most common form of tinnitus is, in all probability, best explained by a vasomotor disturbance of the intralabyrinthine vessels. The "muffled" or "stuffed" sensation may be similarly explained or, like the earache, be due simply to reflex irritation of branches of the trigeminus, as in the case of dental otalgia. He first gives his own case, followed by reports of three others.

The Lancet, July 3, 1909.

High Frequency Currents and Their Medical Application.—C. F. Bailey's conclusions are thus summarized: Experiments on animals and plants and observations on human beings not founded on the individual experimentees' own statements, show that there are *four* marked effects of electric energy produced, uncomplicated by chemical effects, by high-frequency currents: (1) Increased cell activity, increased metabolism; (2) return of a locally inflamed tissue to its normal; (3) either general vascular dilatation or contraction, according to the particular method used, and (4) "inhibition," diminished sensory or motor excitability. So that where one or more of these effects is or are desired and where the remaining effects are not prejudicial, or can be very much diminished or abolished, there high-frequency treatment may be of real value, and for these reasons has a prospect of considerable therapeutic use in the future.

British Medical Journal, July 3, 1909.

Quinine Dermatitis.—A case is reported by W. Gripper, whose patient, a woman known to be very susceptible to the drug, took two-dram doses of a preparation known to contain but one-quarter of a grain to a dram. During the day the rash appeared and spread over the entire body. She was advised to continue with the preparation in the hope that she might become accustomed to it. During the next two days the condition remained the same. The condition was worse at night. She had no headache, and practically no eruption on the face. The drug was then stopped. On the fourth day the hands, legs, and ankles were greatly swollen, the palms red and shining, while the fingers and toes were stiff, feeling numb, and distinctly cold to the touch. Bran baths, etc., gave no relief. By the seventh day desquamation began on the hands and arms, extending to the trunk and legs, the epidermis separating in large strips and flakes with almost casts from the toes. During the fourth week, this was completed and the appearance was like that of scarlet fever. The author adds that his patient has the most unpleasant symptoms if she takes any salicylate of soda.

Aortic Systolic Murmur: Prognosis and Treatment. C. W. Lawson gives epitomized histories of eight cases. Most of them have been in old persons, and the usual cardiac drugs have been of little use. Bromides, however, have been invariably of some service. In the cases of those who died he had been aware of the murmur for four or five years at least before death, so that the final illness did not produce it. It seems to be a commoner condition than books lead us to expect. When he meets with it now he regards it almost as a positively favorable sign of the heart's condition, unless the occupation is very arduous. The cases he has met have not had many symptoms in common. Perhaps the most universal has been a certain excitability of temperament, not necessarily prominent, but easily brought into notice; if the murmur be really due to aortic stenosis this characteristic might be due to some brain anemia. The patients have, however, been quite as often full-blooded people with rather the appearance of having congested brains, and this has tempted him to believe the murmur may be due to the resistance produced by an over-full condition of the vessels in the upper thorax and cerebrum. He is quite sure he has not seen a case of death, in the last seven years at least, from heart disease, with this murmur as the initial and prominent symptom, in any patient under 65 years of age.

A Danger Arising from the Use of Plated Instruments in Ophthalmic Operations.—W. C. Rockliffe refers to a case in which he lost an eye from acute panophthalmitis after extraction. Early on the morning of the day the eye was excised a bright foreign body was noticed floating away with the lotion used for irrigation. It was secured and proved to be a piece of metallic plating which on examination was found to have come off of a pair of scissors used in the original iridectomy. The author assumes that during the iridectomy the fragment had dropped unseen into the anterior chamber or cicatrix and caused the panophthalmitis. No fault could be found with the technique of sterilizing the instruments, and the question arose, could the use of carbonate of soda used in the boiling sterilizer have anything to do with the separation of the plating? It was suggested also that a fault in the copper-nickel plating in the presence of a saline solution might set up galvanic action. This would explain the separation of the plating and the subsequent setting up of the inflammation. The author is convinced of the truth of this theory, and calls attention to the need of great care in examining instruments before each operation.

The Value of Expert Radiography and Cystoscopy in the Detection of Obsolesced Tubercle in the Kidney.—E. H. Fenwick refers to one case, that of a woman in whom radiography demonstrated the presence of rounded renal prominences considered as cysts and full of caseous material like cream cheese. The pelvic space was replaced by fibrous tissue. The ureter was a fibrous cord. The organ was removed and proved to contain such material and to be of the exact size sketched by the author. The surgeon was able to make his positive predictions by the use of radiography and cystoscopy. He knew the patient had tuberculosis somewhere in the urinary tract. Eighteen years ago he had examined her with the cystoscope and found ulceration of the bladder near the right ureter. Later experience has convinced the author that such ulcers signify tuberculous disease of the corresponding kidney. When seen the second time, the cystoscope revealed the cicatrix of the old ureteral ulcer, and it was evident that the ureter was impervious and functionless. The next question was, was the presence of the kidney detrimental? Radiography now determined the presence of the cystic masses above referred to. Catheterization of the left kidney showed evidences of consecutive nephritis induced probably by absorption from the foci in the right kidney. It was therefore deemed advisable to remove the original source of infection. The author says that the kidney is always radiographed for him in two positions: in one the patient takes a deep breath and holds it while the *x*-ray is switched on; the effort thrusts and keeps a mobile kidney down; for the next plate the patient breathes easily and naturally while the kidney rises and falls easily. If the shadow of the organ corresponds in position in the two plates we may know we have a dangerously fixed kidney to deal with. If the shadow had moved, the organ is movable and may be easily dealt with

Berliner klinische Wochenschrift, June 14 and 21, 1909.

The Relation Between Gastric and Pelvic Diseases.—Lewisohn considers the frequency of the complaint of gastric symptoms in patients suffering from various gynecological affections. He investigated the gastric contents of a long series of gynecological patients in the hope of obtaining answers to three questions: In such cases is there an independant gastric disease? Is the stomach complaint caused by some other organic or a general disease? Are the gastric and sexual conditions simply coordinated diseases subordinate to some primary cause. After examining his cases and reviewing the literature he comes

to the following conclusions: (1) Testing the gastric contents during menstruation, pregnancy, and the puerperium gives no clear picture of the secretory function of the stomach; (2) the pathological processes in the genital system stand in a causal relation to the gastric disease in only a relatively small number of the women who complain simultaneously of gastric and pelvic troubles; (3) the gastric analyses of pelvic cases made in different clinics give no uniform results. Sommer of Graz found hyperacidity, Kehler of Heidelberg normal secretion, and Winkler of Berlin and the author subacidity in the majority of the cases; (4) the most divers illnesses of the genital apparatus can be associated with gastric symptoms; (5) as to the etiological relation between the gastric and pelvic complaints, alterations in the general nervous condition of the patient may precede the special nervous disease of the stomach. The pelvic condition may well be the cause of the general nervous condition; (6) therapeutically first of all the general nervous condition must be treated, if necessary by a medical treatment after orientation of the gastric secretions by use of the stomach tube.

The Etiology of Trachoma.—Halberstaedter and von Prawazek describe their experiments on the etiology of trachoma carried out in Java. Owing to the mixed cultures obtained from the eyes of human beings suffering from trachoma they experimented on apes, animals known to be susceptible to the disease. The conjunctiva was roughened and then a few drops of secretion from the eyes of a human trachoma patient dropped into the eyes and the lids massaged. At the end of a week the eyes showed signs of inflammation and the animals developed a conjunctivitis resembling trachoma. Scraping from the conjunctivæ showed the epithelial cells to contain a few granules which stained red in the Giemsa stain. As the disease progressed these granules became more numerous, until they filled the protoplasm of the cells. The authors have been unable to cultivate these organisms and reproduce the disease and so say that the proof of their etiological connection is not absolute. Nevertheless they believe them to be the case of trachoma. The authors claim that they and not van Greeff deserve the credit for discovering the cause of trachoma.

An Organic Hemiplegia in a Young Woman Following Shock.—E. Frank reports the case of a 26-year-old woman who six days after a severe fright developed a hemiplegia without loss of consciousness but associated with headache. After six weeks, movement returned in one finger and gradually the patient improved. Though there were many hysterical symptoms as constant laughing there were definite signs of an organic lesion as unilateral increase of knee jerk, Babinski sign, spastic condition of the leg, and atrophy.

Beneficial Effect of Thyroid Extract on Experimental Tuberculosis.—Frugoni and Grixoni discuss at length the relation of the thyroids to tuberculosis. The gland is rarely the seat of tuberculosis. The gland effects the nourishment of the body, a desired effect in tuberculosis. It increases in size in acute tuberculosis and is often found atrophied in the chronic form of the disease. All agents which injure the thyroid tend to stimulate the advance of tuberculosis. Infants born of tuberculous mothers have thyroids free of iodine. The authors then tested a series of rabbits and found that those fed on thyroid extract were more immune to tuberculosis than the controles.

Münchener medizinische Wochenschrift, June 15, 1909.

Passive Transference of Tuberculous Anaphylaxis.—J. Bauer discusses the three forms of anaphlyaxis, active anaphylaxis due to injection of a foreign substance into the blood, making the animal hypersensitive to a second injection, anti-anaphylaxis the increased resistance to the substance which occurs if the animal survives the second injection, and passive anaphylaxis, produced by injection of the serum of an anaphylaxic animal into a normal one. Simple anaphylaxis is shown by the tuberculin reaction. It has also been shown that repeated injections of tuberculin produces a resistance, or anti-anaphylaxis. The author then investigated the subject of passive anaphylaxis to tuberculosis. He injected the serum of tuberculous guinea pigs and men into normal, healthy guinea pigs. These pigs were thereby rendered anaphylaxic so that injections of tuberculin produced marked febrile reactions. The reaction did not appear if the tuberculin were injected within eight hours of the serum, or when the two were mixed. It occurred only when the serum was injected 24 to 48 hours before the tuberculin.

The Diagnostic Significance of a Diastolic Murmur in Dilatation of the Aorta.—G. Hoppe-Seyler has studied a series of clinical cases and cadavers and states it as his opinion that a diastolic murmur of maximum intensity over the manubrium and extending to the neighboring portion of the right chest, and also heard to some extent in the jugular vein, is a good sign of dilatation or aneurysm of the first part of the aorta and further makes a diagnosis of aortic syphilis probably correct.

Sterilization of Tuberculous Women During Pregnancy.—Martin discusses the effect of pregnancy upon a woman suffering from tuberculosis and considers the advisability of ending the pregnancy and preventing further conception by performing the operation of panhysterectomy on the gravid uterus. He lays down the following rules for the operation: (1) There must be definite physical signs of tuberculosis or the probability of its presence must be made strong by the sudden failure in the patients general condition and loss of weight, following quickly on the beginning of pregnancy. (2) The interruption of pregnancy has no influence if the pulmonary process is far advanced, or the woman is approaching the second half of pregnancy. In such case the procedure is of value only in case of the sudden onset of edema of the larynx or the lungs. (3) Suitable cases for the interruption of pregnancy are those in whom the disease is in an early stage and the pregnancy is in the first third of its course. A valuable aid in determining the suitability of the patient is found in the conjunctival tuberculin reaction. (4) If the interruption of the pregnancy is indicated it should be done under lumbar anesthesia and the simultaneous sterilization and complete extirpation of the gravid uterus should be done.

Deutsche medizinische Wochenschrift, June 10, 1909.

Pseudoparalysis Agitans (Hysterical).—Under this title Müller de la Fuente reports an interesting case. The patient, an English woman twenty-eight years of age, had taken care of her mother, who was a victim of paralysis agitans. During the mother's life the daughter feared she would also become a suffered from the disease. This fear increased after reading in a popular medical book that the disease was not only hereditary but contagious During the mother's last year the daughter watched herself closely, and thought she noticed a slight twitching of the right arm. A physician who was consulted on saying that she did not have the disease was deserted in disgust. After this the condition advanced rapidly. The tremor became stronger and the typical attitude was assumed. The speech became thick. The tremor increased so rapidly and was accompanied by such marked depression that the patient seriously considered suicide. At this time she came to de la Fuente. She was pale and poorly nourished, had a marked tremor and rapid speech, swallowing half her words. She was very emotional. There was a marked "pill-rolling movement" of the right hand. The author, however, did not diagnose paralysis agitans on account of the age, because on one occasion the tremor was equally strong during movement and rest, because there was no fibrillary twitching, and because the disease had made no progress in three years. There were, too, several of the hysterical stigmata. He therefore told the patient that a new cure for paralysis agitans had just been found. This quieted her and gave an opportunity for suggestive treatment. The patient made a complete recovery, and three years later is still quite well.

Is the Powder or Infusion of Digitalis the Better?—Focke reports some studies of the relative efficiency of powdered digitalis leaves and the infusion, and concludes that as one-fifth of the active substances in the digitalis leaves is not soluble the powdered leaves are one-fourth stronger than the equivalent dose of the infusion. He says that this quantitative difference is the only one he can find, qualitatively the powder and the infusion acting similarly.

Tobacco Poisoning in an Infant.—J. Lemaire reported to the Société de Pediatrie a child of one year of age who ate a cigarette containing 1.02 gm. of tobacco, or probably about 0.002 gm. of nicotine. After sleeping for an hour he awoke, cried, and vomited. There was diarrhea, pallor, and cold sweating. Two hours later he was prostrate and drowsy, very pale, with cold extremities, but no cardiac or respiratory disturbances. Tobacco was vomited and passed in the stools. Tea, brandy, and warmth were administered, and at midnight the patient went to sleep. In the morning he awoke quite well.—*British Journal of Children's Diseases.*

Book Reviews.

The New Standard Formulary. Vol. I. Pharmaceutical Preparations, Comprising all Preparations, Official or Included in the Pharmacopœias, Dispensatories, or Formularies in the World, together with a vast Collection from other sources, the whole embracing the entire field of Pharmaceutical Preparations as related to all Schools of Medical Practice. By A. Emil Hiss, Ph.G., and Albert E. Ebert, Ph.M., Ph.D. Chicago: G. P. Engelhard & Company, 1908.

The scope of this work is sufficiently indicated in the title above given. Its plan has been admirably carried out, and the result is a collection of extreme utility to all practitioners of medicine and of seemingly absolute necessity to pharmacists. There are many preparations here contained not to be found in the U. S. Pharmacopœia, the National Formularly, or any of the Dispensatories, mention of which yet occurs more or less frequently in medical literature. A careful examination of a number of the formulæ taken at random is convincing as to the accuracy of the compilation.

Surgical Diseases of the Abdomen; with Special Reference to Diagnosis. By Richard Douglas, M.D., formerly Professor of Gynecology and Abdominal Surgery, Medical Department, Vanderbilt University, Nashville; ex-President of the Southern Surgical and Gynecological Association; Fellow of the American Association of Obstetricians and Gynecologists; Member of the British Gynecological Association. Second Edition, Revised and Enlarged. Edited by Richard A. Barr, B.A., M.D., Professor of Abdominal Surgery, Medical Department Vanderbilt University; Late Major and Surgeon First Tennessee Infantry, U.S.V. Philadelphia: P. Blakiston's Son & Co., 1909.

Perhaps the most important gain to be noted in this second edition over the first, which was favorably reviewed six years ago, is found in the chapter on peritonitis. The editor has wisely retained the charming English of the original, but no fault can be found with the style of the new text. Indeed, throughout the book, so like the original are the editorial additions that it is only by an actual comparison of pages with the other edition that the beginning point of the new matter can be told. This leaves the new volume an unimpaired unit, of which the editor may justly be proud. It is almost unnecessary to say that the quality of the new information is thoroughly up to date and reliable. As example of this the reader has but to notice the changes which have been made in discussing the etiology of hour-glass contraction of the stomach. The editor agrees with Moynihan that this condition is rarely congenital, and has eliminated the classification given in the first edition. No such change, however, has been made in the stated relations of laboratory findings in gastric ulcer and carcinoma, and as these are known to be variable this is to be regretted. This is a small matter, however, and is compensated for by the judicial presentation of the surgical treatment of gastric ulcer. It is strictly fair, rational, and up-to-date, save for one fact—no reference is made to the very important physiological studies on which to-day our entire knowledge of the proper surgical treatment of ulcer is based. Briefly, gastro-enterostomy is not a "drainage" operation, and should not be so described.

Surgical Diseases of Children. A Modern Treatise on Pediatric Surgery. By Samuel W. Kelly, M.D., Professor of Diseases of Children, Cleveland College of P. & S.; Surgeon in Chief Holy Cross Home for Crippled Children; Pediatrist St. Luke's and City Hospitals; Late Major and Brigade Surgeon U. S. V.; President Pediatric Section, A.M.A., 1901; Member Association Military Surgeons of the U. S. New York: E. B. Treat & Co., 1909.

This volume is in every sense something more than a mere chronicle of surgical pediatrics. It strives at and attains a higher goal. There is a clear and consistent effort to present to the careful reader the practical essential differences between child-surgery and adult-surgery; between child-pathology and adult-pathology. Nor is this all—the book is new and up-to-date in the best sense because it not alone gives full credence and value to the importance of experimental medicine and surgery, but painstakingly seeks to make clear the relationship and interdependence of the surgery which in the past has erroneously been called "practical" and that which has with equal error been styled "theoretical" or "experimental." The author has wisely decided that modern surgery must necessarily be a combination of the two, and the skill with which he has woven the intricate woof of modern surgical physiology and pathology into the strong basic warp of well recognized surgical principles seems to the reviewer the most admirable fact of the entire work.

Finally, the author's great care in presenting essential details should be commented on favorably, as, also, and in every case, the reference to drug treatment. Far from omitting this most important matter, the author has devoted adequate space to a presentation quite worthy of the spirit of the book. Possibly the short chapter on club-foot might have been omitted, but its presence does no harm.

A Manual of Volumetric Analysis. For the Use of Pharmacists, Sanitary and Food Chemists, as Well as for Students in These Branches. By Henry W. Schimpf, Ph.G., M.D., Professor of Analytical Chemistry, Brooklyn College of Pharmacy; Member of the American Chemical Society; of the American Association for the Advancement of Science; of the American Pharmaceutical Association; of the New York State Pharmaceutical Association; of the King's County Pharmaceutical Society; of the German Apothecaries' Society of New York City; Honorary Member of the Alumni Association of the Brooklyn College of Pharmacy, etc. With one hundred and two illustrations. Fifth Edition, revised and enlarged. First Thousand. New York: John Wiley & Sons. London: Chapman & Hall, Ltd., 1909.

This work appears in its fifth edition with a new title. It is also much enlarged, its size being increased from 550 pages, 12mo, to 725 pages, 8vo· the illustrations, too, are nearly doubled in number. The book deals chiefly with pharmaceutical and food analysis; the processes described are such as have been tried and found of value. Copious bibliographical references are given, and the index is thorough and complete.

The Psychology of Dementia Præcox. By Dr. C. G. Jung, Private Docent in Psychiatry, University of Zurich. Authorized translation, with an introduction by Frederick Peterson, M.D., Professor of Psychiatry, Columbia University, New York, and A. A. Brill, Ph.B., M.D., Assistant in Psychiatry, Columbia University, New York. New York: The Journal of Nervous and Mental Disease Publishing Co., 1909.

This book is the fruit of three years experimental labor and clinical observation. Jung thoroughly discusses the different views of dementia præcox, and then cites Freud's analysis of a case of dementia præcox. Unlike the former conceptions of insanity, Freud shows that hallucinations and delusions are not at all meaningless and absurd, but have a distinct meaning when analyzed. They are all based on actual previous experiences of the patient. Jung's association experiments fully verify Freud's views; the complex corresponds to the split-off ideas and is subject to the same laws. The fourth chapter lucidly illustrates the similarities between dementia præcox and hysteria, and in the fifth chapter a full analysis is given of a chronic case of paranoid dementia.

The book is epoch-making in psychiatry and a welcome contribution to English medical literature. It shows how to penetrate the mind and throws new light not only on dementia præcox, but on the whole obscure field of normal and morbid psychology. The translation is very faithful and exceedingly good, and the translator's terse and clear exposition of the recent views of the Freud Zurich school is especially worth reading.

L'Asthme (Etiologie, Pathogénie et Traitement). Par le Dr. R. Moncorgé, Ancien Interne des Hôpitaux d'Alger et de Lyon, Médecin-consultant au Mont-Doré. Paris: Vigot Frères, 1909.

This is a careful and exhaustive study of a single disease, and is worthy of close attention by all physicians who are interested in respiratory affections. Dr. Moncorgé considers asthma a symptom rather than a disease; every intoxication, every infection may directly or indirectly produce asthma. This is especially true of rheumatism, the gouty diathesis, and tuberculosis. Every attack of bradypnea, accompanied or not by secretory troubles, is a true asthma. In spite of the apparent unity of syndrome, asthma often is only the total product of diverse associated causes. Clinically there is no such thing as pseudoasthma, one ought to make an etiological or pathogenical diagnosis and say frankly nephritic, or cardiac, or gastrointestinal, or hepatic asthma as the case may be. One-third of the book is given over to treatment, classified according to pathology and clinical forms. The author's clear method of presentation is a very real help in understanding the essential principles of this troublesome affection.

The Matter with Nervousness. By H. C. Sawyer, M.D., Member of the American Medical Association. San Francisco and Los Angeles: Cunningham, Curtiss & Welch.

This little book is addressed "to physicians, mental healers, and patient minds." Its unscientific title may prejudice physicians against it, but it is entertainingly written, if somewhat rambling, and contains many truths. The text seems to be: Scientific medicine affords all the known resources of healing. Why let others find and use them?

Nervousness is treated as "a surface sign of deep-lying bodily deteriorations that are real," and its cure is a struggle requiring on our part time, sympathy, insight into its etiological factors, and character.

Hygiène Oculaire de la Première Enfance. Par le Dr. E. Ginestous, ancien interne des Hôpitaux de Bordeaux, oculiste de l'Hôpital suburbain des enfants. Paris: Vigot Frères.

The work forms a small volume of 114 pages and contains a few tables, but is otherwise without illustrations. In the introduction Ginestous urges that the cause of blindness, like the cause of the high mortality, in children under 15 years of age, lies in want of care or neglect to establish the proper hygiene on the part of those who have the children in charge. He shows by statistics that about 20 per cent. of the blind become so during childhood, and he points out the fact that such sufferers are largely the innocent victims of neglect on the part of their elders. The causes of blindness in children, the hygiene and prophylaxis of diseases of the eye, the refraction of the eye, particularly the importance of progressive myopia and the influence of errors of refraction in the production of squint, are discussed. One chapter describes the congenital defects of the eye. The last chapter is devoted to suggestions regarding the care of blind children. The subject is treated briefly, in a direct, convincing manner, and is written in a semipopular style, so that those who are interested in children, whether of the medical profession or not, may fully understand the text.

A Textbook of Special Pathology. For the Use of Students and Practitioners. By J. Martin Beattie, M.A. (N. Z.), M.D. (Edin.); Professor of Pathology and Bacteriology, University of Sheffield; Hon. Pathologist, Sheffield Royal Infirmary and Royal Hospital; and W. E. Carnegie Dickson, M.D., B.Sc., F.R.C.P. (Edin.); Lecturer on Pathological Bacteriology and Senior Assistant to the Professor of Pathology in the University of Edinburgh; Assistant Pathologist, Royal Infirmary, Edinburgh. With 191 Illustrations and two Colored Plates from Original Preparations. Philadelphia: P. Blakiston's Son & Co., 1909.

In this volume on special pathology the authors have provided a fitting pendant to their excellent work on general pathology recently reviewed in these columns. The present text is characterized by the same compactness and systematic arrangement, and, like its predecessor, bears evidence of much original thought and investigation in the fields with which it deals. The sections on the subjects of more importance, such as the heart, kidneys, liver, etc., are comprehensive and sufficiently detailed for all ordinary purposes, the chapter on the blood being especially noteworthy for its completeness, but it must be admitted that certain other topics are treated in rather step-motherly fashion. For example, a single page barely seems space enough to allow for the diseases of the prostate gland, and even less than this is devoted to the diseases of the penis and scrotum. It also appears a pity that the authors have preferred to omit altogether discussion of the diseases of the female generative system, referring the reader to works on gynecology. The work as now completed, however, must rank as one of the best in the English language, and is fully representative of modern standpoints in pathology. In this volume, as in that on general pathology, the very numerous and unusually excellent photographic illustrations contribute greatly to the value of the work.

Über die Wirkung Moderner Projectile. By Dr. F. Riedinger, Professor at the University of Würzburg. Würzburg: Kurt Kabitzsch, 1909.

This admirable brochure of thirty pages is of much value to the military surgeon, giving, as it does, our first exact information as to the effect on the human frame of the new metal-jacketed sharp point or "Spitz" bullet, recently adopted in all the more important armies of the world, that of the United States included. This bullet is much lighter than the round point metal-jacket bullets of the same caliber used in the Spanish, South African, and Manchurian wars, has an initial velocity of from 20 to 30 per cent. greater, and naturally a much flatter trajectory and increased danger zone. As might be anticipated from its high velocity, this new bullet has very pronounced shattering, or so called "explosive," effect at all but the extreme ranges. Some of these new bullets are not of homogeneous composition, but the posterior third is of softer metal, which expands under pressure to better fit the rifling of the barrel, and which becomes more or less deformed by the blast of the gases as it emerges from the gun. Such expansion and deformation naturally increase the damage done to the tissues struck. The *x*-ray illustrations included in this brochure clearly show that this new bullet can scarcely be considered as humane, and that it will produce bone shattering of even more pronounced and extensive character than resulted from the old style large lead bullets of lower initial velocity. This severity of wounds by the new missile should be clearly understood by military surgeons, lest they fall into the common error, in case of war, that the enemy is using small projectiles of a truly "explosive," and inhumanly destructive, character.

The book is excellently illustrated with *x*-ray plates, and with prints showing the different types of military small arms ammunition in use from 1740 down to the present time. The book is earnestly commended to the attention of all those interested in the surgery of the modern battlefield.

Catholic Churchmen in Science. (Second Series.) Sketches of the Lives of Catholic Ecclesiastics Who Were Among the Great Founders in Science. By James J. Walsh, M.D., Ph.D., LL.D.; Dean and Professor of the History of Medicine at Fordham University School of Medicine; Professor of Physiological Psychology at the Cathedral College, New York; Fellow of the New York Academy of Medicine; Life Member of the New York Historical Society; Member of the National Geographic Society, etc. Philadelphia: American Ecclesiastical Review, The Dolphin Press, 1909.

In this volume will be found the lives of some ecclesiastics of the Roman Catholic Church who have achieved distinction in science. Most of the sketches contained herein have appeared in various periodicals (chiefly religious) during the past few years, and are republished with some revision and additions. The ecclesiastics commemorated are Albertus Magnus, Pope John XXI, Guy de Chauliac, and Regiomontanus. There are also chapters on clerical pioneers in electricity, and the Jesuit astronomers. Catholic physicians and others will find much of interest in the volume; the most interesting chapter for the physician and surgeon is that on Guy de Chauliac.

The Theory of Ions. A Consideration of Its Place in Biology and Therapeutics. By William Tibbles, M.D. (*Hon. Causâ*) Chicago, LL.D., L.R.C.P.E., M.R.C.S., L.S.A., etc. Author of "Food and Hygiene," etc. New York: Rebman Company, 1909.

The author of this little volume presents us with a readable account of the present status of the ionisation theory. He also attributes to the ions certain properties akin to those possessed by living matter; in this way he makes the ionization process a sort of bridge over the chasm between dead and living matter. The book begins with a brief introduction, dealing with the theories of matter, and the characters of living matter. Succeeding this are chapters on The Ions, Ions in Biology, Evolution of Organic Matter, Influence of Ions on the Organism, and Influence of Ions in Oxidation and Immunization. Ample references direct the interested reader to authoritative sources of more detailed information.

The Fluids of the Body. The Herter Lectures (New York, 1908). By Ernest H. Starling, M.D., F.R.C.P., F.R.S., Jodrell Professor of Physiology in University College, London W. T. Keener & Company: Chicago, 1909.

This small volume contains the Herter Lectures for 1908, and an additional lecture which was delivered some thirteen years ago and has been rewritten to fit recent knowledge. In the lectures are discussed the physical properties of protoplasm, the osmotic relationships of the body cells with the exchange of fluids in the body, and the production of lymph. The last lecture concerns the causation of dropsy. The treatment of the subject is fairly simple, and the language in which it is presented is the clear and expressive English which we expect, but do not always get, from our cousins across the water. Many of the facts cited are based upon the author's own experimental researches. It would be well for the practitioner if he read more physiology of this type.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Forty-third Annual Meeting, Held at Cape May, June 23, 24, and 25, 1909.

(Special Report to the MEDICAL RECORD.)

Wednesday, June 23—First Day.

THE PRESIDENT, DR. DAVID ST. JOHN OF HACKENSACK, IN THE CHAIR.

Report of Committee on Scientific Work.—Dr. E. J. MARSH of Paterson said that the committee had decided to limit the number of papers to be read at each meeting to 12, and that it had adopted the policy of securing members to read papers who had not presented papers in previous years.

Report of Committee on Prize Essay.—Dr. CHARLES J. KIPP of Newark announced that the first prize had been awarded to Dr. E. Moore Fisher of Greystone Park, and the second prize to Dr. Floyd McEwen of Newark.

Report of Committee on Medical Defense.—Dr. WILLIAM G. SHAUFFLER of Lakewood made this report: It was recommended that the Medical Society of New Jersey assume the defense of any and all members threatened with prosecution for malpractice, provided they be at the time in good and regular standing in their county societies.

Report of the Board of Trustees.—Dr. LUTHER M. HALSEY of Williamstown made a report of the Committee on Legislation.

Dr. DAVID C. ENGLISH of New Brunswick moved that a special committee of nine be appointed by the president to act in conjunction with the committee on legislation to draft a bill to be presented to the society in regard to the medical situation now confronting them. This motion was carried.

Resolutions Regarding Ophthalmia Neonatorum.—Dr. CHARLES J. KIPP of Newark offered a resolution that the society appoint a committee to put itself in communication with the State Board of Health and component societies to adopt some measures to put a stop to ophthalmia neonatorum. This was referred to committee for action.

Recommendations for Establishing a Home for Idiots.—Dr. CURTS of Paterson asked that the society recommend the establishment of a custodial home for idiots and ask for an appropriation equal to the requirements.

Dr. BRITTON D. EVANS of Greystone Park said that there was no institution in the State for the care of low-grade imbeciles and idiots, and he hoped that the society would give its endorsement of this recommendation. This was referred to the Committee of Legislation.

Oration on Medicine.—Dr. THOMAS N. GRAY of East Orange delivered this oration. He said that, in looking backward, lessons could be learned which should be an incentive to greater zeal in the medical profession. Fear and superstition marked its beginning; it came up through fetiches, alchemy, charms, poisons, and priestly functions to some little knowledge of man and his ailments, having no basis except that there was pain or sickness, and that the sufferers demanded relief from them. Later on, in a quest for the why, there came about some small knowledge of the cause and effect as applied to the human body and its ailments. All through these years there had been self-denial and the assumption of great risks, the giving of life even. All through the civilized world men were giving their brains, their knowledge, their all, for the good of man: this was a spirit of devotion on the part of men of medicine that gave to the history of medicine its salient features, steady advancement in the knowledge and equipment. Dr. Gray detailed a few of the advances made in medicine. In this wonderful advance in scientific medicine how much had they burrowed into chemistry, biology, bacteriology, sanitation, photography, electricity, and the other lesser sciences? The giant strides of scientific medicine during the last decade had been accompanied by a demand for educational standards commensurate with each and every advance. It did not come from the public, but from the medical world. As a consequence the many bogus medical schools of thirty years ago had been reduced to a very few, and the better class of schools had raised their requirements again and again; the requirements for entrance to the fifty-four medical schools in 1910 demanded one or more years of college, these years to be devoted to the study of physics, chemistry, biology, and languages.

Chloroform Anesthesia in Throat Operations.—Dr. F. C. DEMEREST of Passaic read this paper. Chloroform he believed to be the best anesthetic that could be used in operations about the throat in children under the age of twelve years. It should be pure and fresh, given by an expert, and by the drop method.

Dr. GEORGE E. TUERS of Paterson said that he had used five different anesthetics by five different methods. If one took the statistics of New Jersey he believed that the figures would be astounding, showing the large number of deaths that occurred from the giving of anesthetics. Chloroform be considered the pleasantest anesthetic to take, but the most dangerous to use. It was the quickest to anesthetize and the quickest to kill.

Dr. THEODORE F. LIVERGOOD of Elizabeth said that chloroform was being used more and more in throat operations, and the reason was that men were better qualified to give it than they were years ago.

The Influence of Sleep on Arteriosclerosis.—Dr. W. W. BEVERIDGE of Asbury Park read this paper. The whole process in arteriosclerosis seemed to be a failure of nutrition. The pathology of this trouble seemed to focus on this point. Very little work had been done in the study and investigation of the phenomenon of sleep. He believed that sleep had much to do with nutrition; in fact, the couch on which one slept was the repair shop for the body. The system demanded an abundance of good food and plenty of sleep. Those who suffered from arteriosclerosis were generally poor sleepers, their slumbers being disturbed by the cares and worries incidental to the present strenuous life. More sleep would tend to obviate the occurrence of arteriosclerosis.

Annual Address by the President.—Dr. DAVID ST JOHN of Hackensack delivered this address. His topic was "Some Recent Advances in Medical and Surgical Work." He said that medicine and surgery were now becoming an exact science, and many advances had been made. There was a revival in the use of tuberculin in the diagnosis and treatment of tuberculosis. Before the use of Flexner's serum the mortality from epidemic cerebrospinal meningitis had been from 68 to 85 per cent., but since its introduction the mortality had fallen to about 25 per cent. Great advances had been made in the surgery of the blood vessels; also in transplanting an organ of one animal to replace one that was removed by accident or disease in another animal.

Oration in Surgery.—Dr. GEORGE EMERSON BREWER of New York said he would take up the consideration of two subjects—acute unilateral septic infarctions of the kidney, and acute diverticulitis of the colon. Acute unilateral septic infarction of the kidney was a condition that was not generally recognized, as evidenced by the fact that of nine more or less typical examples of the disease which had been admitted to Roosevelt Hospital during the past four years only one came in with the diagnosis of a renal infarction. This condition was first called to his attention

twelve years ago, when a case was admitted to the New York Hospital. During the next five years two more cases were encountered, each almost identical in onset, clinical history, and pathological findings. In all of these cases the kidney was explored, incised, and drained. The patients all died. Up to this time he feared to perform nephrectomy, for the reason that he thought the infarctions were bilateral, although the symptoms pointed to one side only. The next case was more carefully studied, and the autopsy gave him his first definite conception of the true pathological lesion and clearly pointed to more radical treatment. This case, together with his previous experience, conclusively demonstrated to him that in these cases he had to deal with a severe type of infection, presenting an obscure symptomatology, which tended to progress rapidly to a fatal termination unless something far more radical in the way of treatment was employed than had been carried out in his earlier cases. The lesions most commonly found in these cases were due to a plugging of the smaller arteries and capillary vessels with groups of organisms. These minute emboli were later surrounded by an encircling zone of round cell infiltration. When the larger trunks were thus involved triangular infarcts were presented; where the capillaries only were involved, minute abscesses were seen throughout the cortex and beneath the capsule. Dr. Brewer then described three clinical types of the infection. One, the severe type in which the toxemia was so great as to obscure the comparatively mild renal lesion. This type progressed rapidly to a fatal termination unless promptly treated by nephrectomy. There were thirteen cases of this type which came under his observation, of which five were treated by nephrotomy with death in every instance; eight were treated by nephrectomy and all recovered. The second was the intermediary type, and in this the initial symptoms might be as severe, but the evidence of grave, progressive toxemia was wanting. Six cases of this type had been operated upon by him; all were decapsulated and all made satisfactory recoveries. The third was the mildest type of the disease; no operation was required and the patients were of surgical interest only on account of the fact that it accounted for certain cases observed by all surgeons in which during or after a presumably typical attack of subacute appendicitis or cholecystitis an operation revealed no lesion or signs of inflammation. The one pathognomonic sign in all cases was a marked unilateral costovertebral tenderness. Acute diverticulitis of the colon he divided into four clinical groups. One in which there was a mild inflammation of the diverticulum which subsided like a catarrhal appendicitis under rest and appropriate medication. Secondly, those cases in which the inflammation was more severe and progressive and in which the diagnosis was made and operation performed before rupture took place. Thirdly, those cases in which there had been a rupture of the diverticulum with the formation of a localized abscess. Fourthly, all cases in which rupture of the inflamed diverticulum into the free peritoneal cavity had taken place with a resulting spreading or generalized peritonitis. In general it might be stated that the symptoms and signs of an acute diverticulitis were practically identical with those of an acute appendicitis in its various forms, the only difference being that the former occurred, as a rule, on the left side rather than on the right side of the abdomen. The clinical course of the disease was so similar to the various forms of acute appendicitis that the treatment should be the same.

Intramuscular Mercurial Injections in Syphilis.—Dr. Henry A. Pulsford of Orange said that in the administration of mercury by mouth or inunction there was no indication to tell one how much reached the general system. There was no doubt regarding the merits of the intramuscular injections of mercury. The physician's control of the patient was perfect. Of all the objections against the use of these injections, the most common was that it was painful. This was not always so. About the point of injection there was formed an organized or unorganized exudate which was called "nodes." If too many of these formed, then there was danger from mecurialism. In case the patient had an extensive dental caries this was a contraindication for the use of mercury.

Dr. J. F. Wallhauser of Newark believed that the intramuscular injection of mercury in the treatment of syphilis would be the plan of the future. He began this treatment five years ago and had never seen any disagreeable features except from the painful nodes. The use of the gray oil was less painful he thought than the salicylates.

Dyspepsia a Misnomer.—Dr. W. Blair Stewart of Atlantic City said that dyspepsia was not a disease but a symptom. The term dyspepsia was an unfortunate one. Dr. George B. Wood in his book written in 1847 said that the term was a most unfortunate one as it expressed no pathological state. This term should not be used in order to shield ignorance. He reviewed the modern diagnostic methods and made a plea for early and accurate diagnosis of cases.

Dr. J. Finley Bell of Englewood believed that the word dyspepsia was not used to-day as it was a few years ago since the diagnostic methods had become so refined.

Thursday, June 24—Second Day.

Address of the Third Vice-President.—Dr. Daniel Strock of Camden made this address on "Problems that Confront the Component Societies." He emphasized the importance of medical representation in city, state, and county affairs, not so much for what benefit might accrue to the profession, but for what might be done for the good of mankind. Contract and lodge practise was strongly condemned. The opportunities for doing good were to be had only through a hearty cooperation on the part of the doctors in the component societies.

The Indications for the Induction of Labor: Instrumental Delivery Through the Vagina and Cesarean Section.—Dr. Edward P. Davis of Philadelphia read this paper. He said that cases of parturition should be divided for the purpose of study into those who had passed through either one parturition at full term and those who had not passed through parturition at full term. In the case of the former every effort should be made to prepare the patient for spontaneous delivery. Unless the pelvis was highly contracted, labor should not be induced, because 80 per cent. of the patients with abnormal pelves of lesser degrees of contraction delivered themselves spontaneously. During pregnancy these patients should receive careful attention in order to bring them to labor in the best possible condition. In four-fifths of the cases of pelvic contraction the child spontaneously entered the pelvis and in nine-tenths of all cases of primipara this result occurred from natural causes only. In those cases where the women had passed through unsuccessful parturition an effort should be made to select a method of delivery in accordance with former experiences. In selecting the time to induce labor two methods were of practical value. One consisted in fitting the presenting part into the pelvis by suprapubic pressure coupled with a vaginal examination to determine the result. The second consisted in taking the average period of gestation and to bring on labor at that time. Thirty-four weeks had been found to be a good average time for the induction of labor. In selecting instrumental delivery through the vagina the most frequent operation performed was extraction by the obstetric forceps. One could not too strongly condemn the application of forceps to the head which was not engaged in the pelvis. The engagement of the head would

be furthered by placing the patient during the second stage on that side of the body towards which the back was directed, by causing the bladder to be frequently emptied, by preserving the membranes intact, and by giving a stimulus, as well as rest to the nervous system. When the head was engaged without descent and the operator decided to use forceps, Walsher's position would aid all women younger than thirty-five. The operation of version had fallen into some neglect during the development of other methods of operating. Under the most favorable circumstances the induction of labor threw a distinctly increased risk upon the child. The maternal mortality of embryotomy did not depend so much upon the operation as upon the unfavorable circumstances surrounding it in those cases in which it was indicated. Where the disproportion between the mother and the child was slight, where the vagina was very distensible, or had been distended by previous labors, where the mother and child were in good condition, and the life of the child was desired, symphysiotomy or pubiotomy done in the hospital with good technique gave fairly good results. In summarizing, Dr. Davis said that except in cases of highly contracted pelves, or where it was impossible for the presenting part to engage, the patient should have the test of her first labor. In the majority of the cases engagement and descent began, and labor was safely terminated by vaginal delivery. Where there had been a disastrous first labor ending in injury or death to the child and injury to the mother the cause should be carefully sought. If a disproportion in the size had been the cause, the mother's diet should be carefully chosen and, if the child was evidently large, labor should be induced on an average of about the thirty-fourth week. If the parents were anxious for a child, the mother's diet should not be restricted and labor should not be induced, but the mother should be put in the best possible condition and allowed to come into the beginning of labor. When it was evident that engagement and descent were not occurring normally, the child should be delivered by abdominal section. Forceps should not be applied to the presenting part unless the latter was engaged and beginning to descend through the upper pelvis. When this did not occur the life of the child was to be considered, and if a competent operator and hospital facilities could be secured the patient should be delivered by abdominal section. If the patient was a multipara and the disproportion was very slight, and the vagina was distensible and a competent operator at hand with hospital facilities, a pubiotomy, if desired, might be selected. When an engagement of the head had not occurred and the operator was unwilling to assume a reasonable risk for the life of the child, the case might be terminated by an embryotomy. Abdominal section should not be done in those cases where efforts had been made to deliver the child by forceps, version, or embryotomy unless the operator was prepared to remove the body of the uterus. Those cases in which unsuccessful efforts had been made by vaginal delivery should be considered as infectious; the conditions were unfavorable for abdominal delivery, and the child should be extracted by embryotomy and the uterus drained with gauze. Where there was reason to fear that the uterus and surrounding tissues had been injured and ineffectual attempts at delivery had been made, an abdominal section followed by the Porro operation should give the best results. Dr. Davis desired to emphasize the following points: (1) The forceps should not be applied to the presenting part unless engagement had occurred and descent begun. (2) Delivery by abdominal section should not be performed in those cases where inefficient attempts at delivery by forceps, version, or embryotomy had been made, unless the operator was prepared to remove the body of the uterus.

Indications for Interference During Labor.—Dr. Simon Marx of New York presented this paper. He said that when and how to operate during labor were gifts possessed by few obstetricians. The best operator was the one who possessed the faculty of knowing both how and when to interfere. The following essentials held the crux of the situation: (1) The study of the woman before labor. (2) A positive appreciation of the position and presentation of the fetus and its relation to the pelvis. (3) The constant control of the fetal heart's action and the maternal condition. (4) Interference only when there were positive indications which warranted such interference. In studying the woman from the standpoint of pelvimetry, the pelvic contractions and irregularities, especially the latter, could be determined by the pelvimeter, and the use of this instrument should be encouraged more. If a relative or absolute pelvic contraction could be excluded, a case of dystocia must of necessity be due to a malposition or malpresentation of the presenting part in an overwhelming majority of the cases. The head that failed to engage was either malposed or too large for the pelvis. The constant regularity of the heart's beat was of unquestionable value in estimating the safe life of the unborn child; on the maternal conditions they pinned their faith mainly on the condition of the pulse and the temperature. No labor should be interfered with unless there were present symptoms of beginning maternal exhaustion or fetal exhaustion. Should either one or the other of these manifestations present, labor must be terminated to save the fetus. In a canal that was prepared, a rapid delivery was simple and safe, both for the mother and the child. But if the conditions were otherwise, he believed in the following: Placing the life of the mother and the child on the same plane, where a cutting operation was to be done, a Duhrssen's operation or a vaginal cesarean section would be the measures at their command. To attempt to deliver the fetus rapidly, no matter what the indications were, simply defeated their own ends, and to this was added the risk to the mother. To successfully cope with such an emergency as a sudden irregularity of the fetal pulse and a discharge of meconium in a woman whose os was hardly distended, he asked if they were justified in subjecting the woman to the risk of a serious operation in order to attempt to deliver her of a living fetus. Could they operate quickly enough or deliver sufficiently rapid to succeed without producing dangerous lesions? Personally, Dr. Marx thought not. It would subject the operator to a very uncomfortable position to deliver a dead or dying fetus under these conditions, after subjecting the woman to all the risks of operation, plus the usual lack of preparation. Where the canal could be easily dilated for rapid work, it should be done; but under all other conditions he favored the waiting policy. Correct any anomaly of uterine obliquity and by placing the woman persistently on that side corresponding to the position of the presenting part at once favored flexion in vertex cases and extension when the face presented. This might or might not be supplemented by direct finger pressure to insure the completeness of either flexion or extension. The posterior occiput cases could be corrected by version, by rotation of the entire head with the body into a perfect occipito-anterior position, but how seldom did this correction, when possible, remain permanent? Version was more preferable than head rotation; but how often could it be done? He advised letting these cases alone until indications for interference arose. Where all the physical causes could be excluded and the labor was tardy and the pains faulty, there was no better oxytocic to regulate the pains and increase their efficiency than one or two grams of quinine by either mouth or rectum. When an examination revealed a neurotic or spastic condition of the os, with sharp edges, there was no better means at hand than chloral in divided doses up to three grams.

Opium was of good service early in such cases during the first stages where there was danger of lagging pains and exhaustion.

Dr. J. Watson Martindale of Camden said there was no method of determining the exact size of a child's head before birth, and he reported the case of a woman giving birth to her child naturally, and on the operating table, while preparations were being made for doing a cesarean section.

Dr. Ellis W. Hedges of Plainfield said that delivery was often hastened, especially in the larger cities, for the convenience of the operator, and not always for the good of the patient.

Dr. Edward J. Ill of Newark recalled two cases in which high forceps operation was done, and in both cases the pubic bones had been separated. In one case there resulted an incurable vesicovaginal fistula; in the other cases a vesicovaginal fistula resulted which had been operated upon three times unsuccessfully. Both these patients were made invalids for life.

Dr. Norris of Philadelphia believed that no man had any right to attend a confinement in a primipara without a knowledge of the size and the shape of the pelvis, or in a multipara without a study of the patient, a history of her former labor or labors, and a knowledge of her physical condition. In forceps delivery, when the third stage approached he removed the instruments and allowed the woman to come out of the chloroform and deliver herself. By so doing there would be less hemorrhage and fewer complications. He thought that the infant's claim for life should be heeded and operations more often resorted to. Whenever the conjugate diameter was less than 8 cm. he believed in elective operations. Cesarean section was indicated in cases of placenta previa where an early diagnosis had been made, with a patient not exsanguinated, with a child that was viable, with good environment, and with a skilled operator at hand.

Medical Expert Testimony.—Dr. Thomas P. Prout of Summit read this paper, in which he made a strong argument against medical expert testimony as it existed to-day. He urged an expeditious reform. There was too slow an administration of justice. He was asked to testify in a case recently; when he asked how soon he would be needed he was much astonished at the reply, "In about three years." It seemed to him that the law of the future must take on a more scientific aspect if it intended to keep up with the progress of the world.

Dr. Britton D. Evans of Greystone Park said that the particular reason for introducing hypothetical questions in the trial of a case before a court and jury was for the purpose of setting forth in a more or less abstract way the scientific facts and conditions identical with or similar to those which had been proven or were to be proven in the given case at issue; and the extensive hypothetical question had been ordered because it set forth in a most expeditious manner all the admissible parts in the testimony needed. Personally, he found the hypothetical question in many particulars objectionable in that it grouped together a number of hypotheses, and forced the witness to accept them all as proven facts and to reject all other minor testimony not included in such hypothetical question. It was firmly his belief that long hypothetical questions, consisting of several thousand words, did not contain the best advances in the cause of justice; they tended to bewilder and confuse.

Dr. Edward J. Ill of Newark thought that the reader of the paper deserved great credit for his criticism of the law and its officers. He wished for the abolishment of hypothetical questions. The intimidation of witnesses should not be permitted. They should ostracize those among them who contributed to the miscarriage of justice.

Election of Officers.—*President,* Dr. B. A. Waddington of Salem; *First Vice-President,* Dr. Thomas H. Mackenzie of Trenton; *Second Vice-President,* Dr. Daniel Stock of Camden; *Third Vice-President,* Dr. Norton L. Wilson of Elizabeth; *Corresponding Secretary,* Dr. Harry A. Stout of Wenonah; *Recording Secretary,* Dr. William J. Chandler of South Orange; *Treasurer,* Dr. Archibald Mercer of Newark. Next place of meeting, Atlantic City.

Pathognomonic Signs Relating to Appendix Localization.—Dr. A. J. Walscheid of Union Hill read this paper and offered the following conclusions: In making a diagnosis of appendicitis it was essential (1) to take into consideration the previous history; (2) the character of the pain, whether general or local; (3) the presence of gastric disturbances and bowel movement; (4) the presence of bladder, rectal, respiratory, and other symptoms; (5) the degree of contraction and tenderness, with a careful mapping out of the points of most severity; (6) the leucocyte count, temperature, and pulse. Edenataus condition of the parietal peritoneum involving the ileopsoas fascia and muscles produced a sign which was important in making a topographical diagnosis. It was brought about by an inflammatory irritation causing muscular rigidity, and was exhibited by the patient complaining of pain with moving the right leg and keeping the thigh continuously flexed upon the abdomen to bring about muscular relaxation. In the beginning of an attack of appendicitis this sign might be overlooked; but as the disease progressed it presented itself in mild degree, and gradually assumed a more severe type.

The Sterilization of Confirmed Criminals, Idiots, Imbeciles, and Other Defectives by Vasectomy.—Dr. William J. Chandler of South Orange said that students in sociology had called attention to two important facts—that the birth rate of the criminal and defective classes increased much more rapidly than did that of the intelligent and law-abiding citizens, and that certain defects were passed along as an inheritance from the parent to the child. The statistics showed that criminals, imbeciles, idiots, rapists, and the insane multiplied twice as fast as the rest of the population. There were several reasons for this increase, and the most obvious laid in the fact that these defectives had no sense of their responsibilities and sought only a gratification of their animal nature, while the more intelligent classes realized their responsibilities and the burdens entailed in raising families, and so limited the number of their offspring. The forbidding of marriage would not help; marriage was not necessary for the propagation of children, for many were born out of wedlock. The segregation of these people in colonies was too costly. Castration unsexed the individual, and therefore was objectionable. The *x*-ray was known to produce sterility in a large number of cases, but their knowledge was limited, and it would take considerable experimentation to determine its effects in this respect. Dr. Chandler said there was one safe and thoroughly efficient operation to prevent the propagation of criminals, idiots, imbeciles, and other defectives, and yet not unsex them, namely, vasectomy. This was a simple operation, and could be performed under a local anesthetic or none at all. The power of self-control was said to be increased by preventing the absorption of the testicular secretion. He hoped that a resolution would be passed to prepare a bill on the lines of the one framed in Indiana to be presented at the next session of legislature.

Dr. George H. Balleray of Paterson said that crime and its punishment properly came within the province of preventive medicine. If the race was to be improved, the criminal element must be eliminated. The only efficient way to prevent crime was to unsex all criminals. There was nothing that would act more powerfully than the fear of being unsexed. Crime was fundamental in order to obtain the means of satisfying the sexual propensity. A

man would incur any risk to satisfy his sexual instincts, and this made him a source of danger in the community. When a man allowed his sexual passions to override his judgment he reduced himself to the life of a brute, and should be so treated. After he had been unsexed such a man became a better citizen, and might become a very useful member of the community. When one considered the perfect abandon with which the modern woman submitted to evisceration of her pelvis by her pet gynecologist, he concluded that the fear of being unsexed would not act as a means of deterring from crime so far as the woman was concerned. But the thought of being rendered sterile would prevent them from propagating offspring, that would inhibit their tendency, and in that way diminish the number of criminals. For that reason the female criminal should be treated as their male companions in crime. The suppression of immigration came within the province of preventive medicine. If America was to be the dumping ground of all the riffraff and scum of Europe, we must expect physical and moral degeneracy as a reward for our utter disregard for the consequence of our asinine behavior. Why should America open its doors for the vagabonds, paupers, and criminals that Europe saw fit to unload on our shores? What was to become of the American people if this state of affairs was to continue?

Friday, June 25—Third Day.

At What Age Should a Child Be Admitted to Our Public Schools?—Dr. Joseph Funk of Elizabeth said the law read that children over five and under twenty years of age should be admitted to the public schools. He believed that no child should be admitted under the age of seven years; that the length of the school hours should be shortened, especially during the first two years of school life; that outdoor games should be encouraged; that every child entering school should be carefully examined by a school inspector, etc. It was no wonder that the children fell a prey to disease after spending long hours in rooms containing fifty or more children, and that the mortality among them was so high. Before thinking so much of their mental training, more attention should be given to their physical training. They should be more in the open air and in the sunshine. Plenty of sleep was also essential.

Some Points in Infant Feeding.—Dr. D. E. English of Summit said that infant feeding was not yet an exact science nor a perfect art. The final result to be striven for was a mentally and physically perfect adult. With regard to the kind of food given he had very little to add, but he advocated mixed feeding. When the mother's milk was deficient the child should nurse all there was, and then be given the bottle immediately to finish the meal; in this way the artificial food would be influenced by the ferments in the mother's milk. The babe should be put to the breast at once after it had been washed and given nothing but water until the milk appeared in the breasts. The babe should have plenty of sterile water between feedings; raw water was better if it was sterile. The baby's hands and everything he touched should be kept as clean as possible. The inside of a healthy baby's mouth should not be washed until the teeth appeared. When the infant had two incisor teeth one could begin feeding cereal water. The cereals should always be boiled three hours. A week later egg-albumin water could be given; the white of one egg to one half-pint of water was strong enough. A little salt, and possibly some milk sugar, might be added. From the third month fruit juice, preferably orange juice, should be given twice a week. One could begin weaning the infant when he had four well-developed teeth. Night feeding should be first omitted. Weaning should be a slow process, extending over six or eight weeks, and if indications for weaning came in the hot or humid season it might be well to defer it or to wean only partially. Clean raw milk was better than pasteurized milk; middle milk might be used or the cream might be pasteurized. It was safer to sterilize the milk sugar. The tendency was to use too high percentage of fat and protein and to overfeed. The infant would fail to grow on too rich food just as surely as on too poor food. Raw yolk of egg might be begun at the end of the third month, a quarter of a dram once a day. This quantity might gradually be increased, until by the seventh month one dram twice daily was given. One should always add a little salt to modify milk and suit the infant's taste. No hard and fast rules could be given as regarded the amount of food. The capacity of the infantile stomach was not accurately known, and each infant was a law unto itself. The infant was the best judge of how much it should take at each feeding. They required a little more modified milk than mother's milk. The only safe guide was the increase of weight and length in proper proportion. One should not try to make an infant grow much during hot or humid weather, but should be content with keeping it hardy and well. In regard to the manner in which food was given, one should remember that one object was to develop the muscular power of the stomach. This could only be done by properly exercising that muscle. Too frequent feeding, not feeding too much at one time, was the cause of dilatation of the stomach. Feeding a fixed amount at certain regular intervals, with mathematical exactness, was a mistake; a baby was not a machine—it was vital, not mechanical. The infant could not always digest the same amount of the same kind of food in the same number of minutes. An infant should never be fed when it was not hungry. Never feed the infant until nothing else would quiet it. Try water, fresh air, adjustment of clothing, then let it cry and worry for a time; be sure it was hungry. When the infant was feeding try to induce it to continue feeding until its stomach was full and distended. It did no harm if a little ran over. This stretched and exercised the stomach muscle. After the infant had taken all the food that it could be induced to take it should sleep. Everything should be done to prolong this sleep as long as possible. The child should not be fed again until nothing else would quiet it. Ample time should be allowed for digestion, complete contraction, evacuation, and rest.

Ophthalmia Neonatorum.—Dr. T. Richard Paganelli of Hoboken said that one-fourth of all the cases of blindness was due to ophthalmia neonatorum. The partially and totally blind, according to the United States Census for 1900, equalled 7,369. Ophthalmia neonatorum was probably the cause of 25.02 per cent. of the blind in the first year of life. In Great Britain, in 1880, 7,000 persons lost their sight from this disease, costing the government 350,000 pounds annually to maintain them. From a commercial point of view one could readily see the benefit it would be to stamp out this disease, which was both preventable and curable. The best method of prevention was that instituted by Credé, which was as follows: Remove by washing with sterile water the collection of vaginal discharge on the infant's eyelids; the eyelids were then separated and a drop of a two per cent. solution of silver nitrate was instilled. The following were Credé's own figures: 1880, 211 births; cases of ophthalmia neonatorum, 0; a percentage of 0.00. 1881, 400 births, cases of ophthalmia neonatorum, 0, a percentage of 0.00. 1882, 418 births; cases of ophthalmia neonatorum, 1-2; a percentage of 0.25—0.49. 1883, 131 births; cases of ophthalmia neonatorum, 0; a percentage of 0.00. Bayer had stated that from 1877 to 1880 ophthalmia neonatorum in Stuttgart, Germany, was from 8.7 to 14.3 per cent. Since the Credé method had been instituted there had not been a single case.

The Super-Nutritive Properties of Milk.—Dr. Alex-

ander McAlister of Camden read this paper. He said that if an apology were demanded for presenting what seemed at the present time to be the most hopeful features of the pure milk propaganda from the viewpoint of the physician, the mention of recent developments and the fact that almost alarmingly little was being written on the subject should suffice. The sanitary sciences and the campaign against tuberculosis seemed to have crowded the great problems of infant feeding and how to secure a purer general milk supply to the rear. This was to be regretted, because pure milk was a requisite in the treatment of tuberculosis. The tendency to consider milk in its purely biological aspects was at once the most recent and the most auspicious, because it showed milk to be the most extraordinary of foods, and it demonstrated the difference between pure whole milk and milk that was not pure and whole. This new aspect of milk gave the strongest incentive yet entertained for shortening to the minimum the interval of time between the milking of cows and the ingestion of milk. Centuries ago the opinion was entertained that mother's milk possessed properties not embraced under the head of nutritive principles. This biological principle in milk over and above the strictly nutritional gave to milk its distinctive character as a food. Other foods were more fattening, but none was so well suited to the needs of the growing organism. Because of the presence of this principle, milk was of the nature of mixed food in the sense that it contained all five of the essentials of a perfect food; it was digested with the ease of a simple food, with very little residue to be disposed of by the intestines. Thus milk met, as no other food could, the special demand in the infant for rapid constructive metabolism and growth. Milk was an extraordinary food in the sense that it was made available by nature, unaided by man, to meet specific needs in nature. If these needs were those of an infant, this statement was only applicable to the mother's milk. Cow's milk was ideal only for calves. Still it was a superb fact that cow's milk was the best of all available foods for infants deprived of breast milk. Substitute feeding always added an element of danger, but the danger was least when cow's milk was employed. The aim should always be to derive from the milk all that nature centered in it for the benefit of the youth. The extraordinary properties of whole pure milk, stripped of the verdant laboratory phraseology, lay in its close kinship to blood. Formerly, milk was looked at as a natural emulsion; to-day it was regarded rather as living cells suspended in serum. The cells were nucleated, and if not genuine white corpuscles were at least first cousins of the white corpuscles. The property that stimulated and facilitated digestion and assimilation, perhaps even metabolism, the power that restrained, if it did not destroy, bacterial activity and other more subtile, if not more important, qualities were explained by this blood kinship. These supernutritive principles in milk were always the first to suffer when change occurred in the milk. These supernutritive principles were found only in fresh, whole milk; in stale milk overrun with bacteria and in boiled and preserved milk they were no longer present.

Amebic Dysentery in California.—J. D. Long considers that amebic dysentery has a firm foothold in California. He recommends for its eradication: (1) Legislation making it a punishable offense to use human excreta as fertilizer; (2) inspection of gardens, truck farms, etc., to see that such a law is enforced and the licensing of gardeners, all cases and crates bearing the license number; (3) education of the people to the knowledge that fresh vegetables must be thoroughly cleaned and cooked; (4) inspection of water sheds; and (5) proper disposal of sewage.—*California State Journal of Medicine.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 17, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	480	158
Diphtheria	250	27
Measles	501	13
Scarlet Fever	107	8
Smallpox	—	—
Varicella	13	—
Typhoid Fever	60	8
Whooping Cough	47	12
Cerebrospinal Meningitis	7	8
Malarial Fever	..	..
Totals	1,465	234

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 16, 1909:

		CASES.	DEATHS.
SMALLPOX—UNITED STATES.

PARASITISM AND NATURAL SELECTION.

A MEDICAL SUPPLEMENT TO DARWIN'S ORIGIN OF SPECIES.

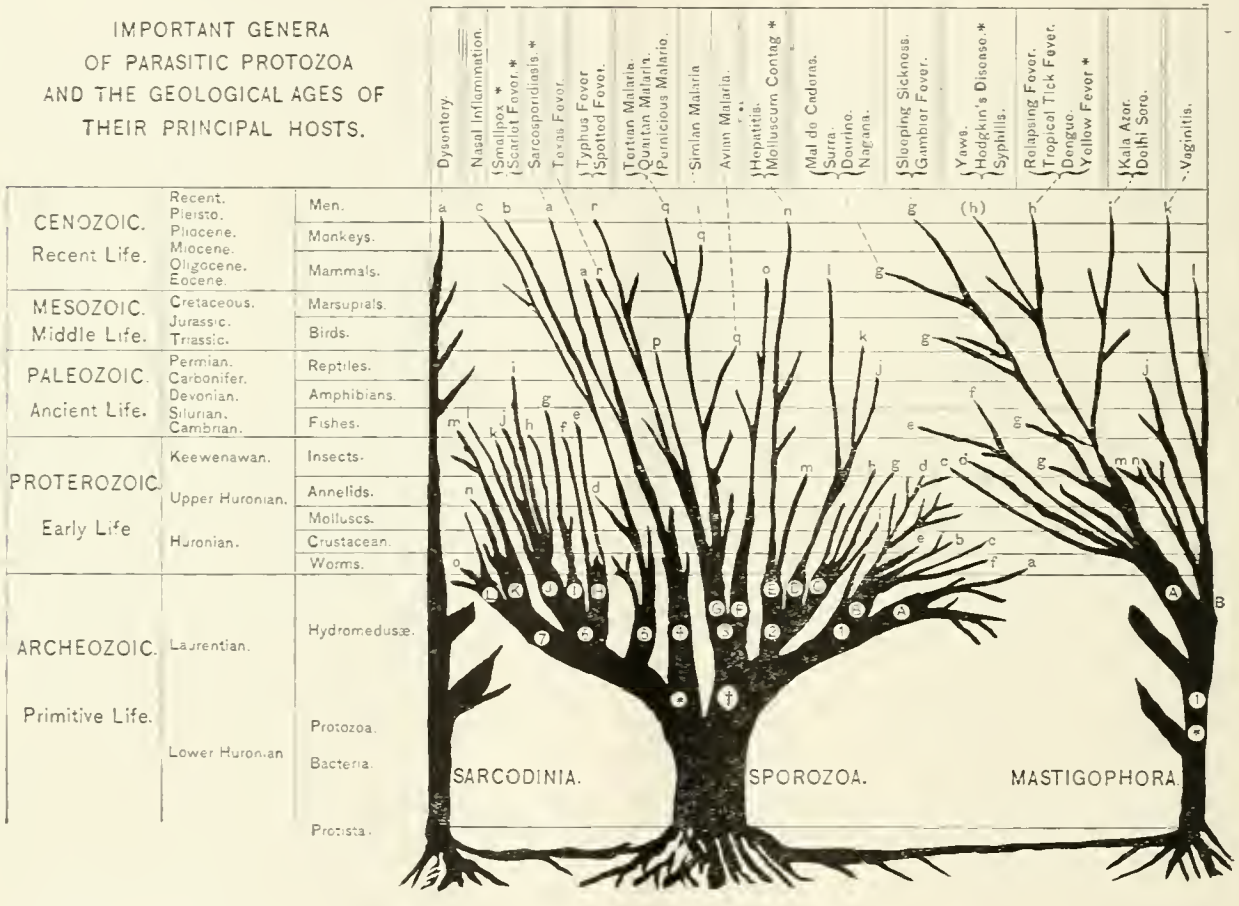
By R. G. ECCLES, M.D.,

BROOKLYN, N. Y.

Fifty years ago, when Charles Robert Darwin published the first edition of his, now, justly famous book, "The Origin of Species," nothing was known of the part played by parasitic microorganisms in the struggle for existence. At that time conditions of ill-health were looked upon as due to miasmatic effluvia, dampness, cold, and other climatic causes. An unavoidable consequence of looking at things from this faulty viewpoint was that all of his evidence, and all of his deductions, had almost exclusive reference to the struggle of the higher forms of living things with one another. He took no notice of that deeper and more subtle form of struggle that is going on between disease germs and tissue cells. This, though the most profound phase of the Struggle for Existence, among higher animals and higher plants, was entirely unknown to him and was, of necessity, totally overlooked and absolutely neglected. Starting, as this phase did, at the very beginnings of that part of the warfare that is of chief importance to us it could not but be connected with the earliest causes that fixed the trends of variations and led up to the higher organized forms. It was also the nearest in character to a purely Malthusian fight, such as constituted Darwin's ideal of the battle of life with life, for a supply of food. Biological surfaces were then all that could be seen. The great depths had not been explored. His conceptions of competition, as stated by Prof. F. E. Clement, "were drawn largely from Lyell and Herbert, and he was content to take it as a universal and fundamental process among living things, without detailed inquiry into its working or its precise relation to the origin of new forms."[1] He chose as his viewpoint the best that his generation could supply. The fact that it was inherently defective can cast no discredit upon him.

In the year that the "Origin of Species" was published (1859) Louis Pasteur, then a young man of 37, was at work in the Ecole Normale, Paris, laying the foundation for a new and better conception of the breadth and depth of the species-making forces which Darwin's theory implied. It was not, however, until 1865 that the truth began to dawn upon Pasteur that in disease we have a battle royal, between life and life, for food. The silk industry of France was then threatened with extinction by a virulent plague that was killing the worms in a wholesale manner. The government representatives had been called upon for help and they sought advice from Dumas. The latter turned to Pasteur, as the one man in all the world likely to be able to benefit the people in that hour of financial peril. Pasteur at first hesitated to act but Dumas insisted, feeling confident that the man who had solved the problem of fermentation, in a way so thorough as to defeat Liebig, must be the right sort of man to face a subject so beset with difficulties. In a few weeks Pasteur had formulated a germ theory of the cause of the trouble but it took him five years to demonstrate its truth. The worms were, finally, found to be suffering from the attacks of two kinds of pathogenic microorganisms—those of pébrine and those of flâcherie. In this remarkable piece of pioneer research work he opened the door which has led us to modern pathology. In 1870 he published two volumes on diseases of silkworms in which he gave the world its first glimpse of the kind of battle that constitutes the most fierce phase in the Darwinian Struggle for Existence. Then, however, there was no appreciation of the fact that he was dealing with an important part of the problem of natural selection. It took years for us to see any particular connection between his work and that of Darwin. Indeed, there are still many intelligent people into whose consciousness this idea has not yet penetrated. Up to about 1880 it had hardly been dimly realized by our best thinkers. The earliest, unequivocal statement of it, that I have been able to find, is that of Prof. H. Gradle of Chicago, who in 1883 wrote that, "In the light of the germ theory, disease is *a struggle for existence between the parts of the organism and some parasite invading it.* From this point of view, diseases become a part of the Darwinian program of nature."[2] The author evidently felt that he was presenting what was then a novel idea or he would hardly have taken the pains to italicize so many of his words. A more recent author, whose volume lies before me, gives expression to the idea in this way: "The microparasites of disease are an integral part of organic creation. Like all other living creatures they are subject to the laws of evolution, of the struggle for existence, of the survival of the fit."[3] During the last decade such statements have become common but in no instance known to me has any writer tried to show that if this is true our structures must, in great part, be a resultant of disease action. Nor has any one pointed out to us that failure to incorporate this view into our evolutionary reasoning must lead to erroneous conceptions regarding the relations of certain kinds of phenomena to natural selection. To look upon disease as of trivial importance, when it may, in fact, be the one thing of greatest importance, is to put a Darwinian at a serious disadvantage when called upon to explain some apparent exception to the law. If the multiplication table stood in the way of biased ideas, like some that Darwinism has to face, there can be little doubt but that flaws would be found in it. No law of nature can ever be known with such perfection

that apparent exceptions cannot be discovered. Even of the great law of gravity we are told that "Newton, though he had the highest confidence in its truth, admitted that there were motions in the planetary system which he could not reconcile with the law."[4] Le Verrier and Adams cleared up one such difficulty by directing Galle where to turn his telescope in order to discover the unknown planet that was causing it. In this way Neptune was discovered and Newton's law vindicated.[5] H. Sainte-Claire Deville questioned the truth of the law of Avogadro—the law upon which is now built that vast scientific structure known as Organic Chemistry—because of its apparent irreconcilability with the behavior of the compounds of phosphorus, arsenic, antimony, and nitrogen at the temperature of volatilization. Cannizzaro, Kopp, and Kekule showed that the whole trouble was due to their decomposition at such a temperature.[6] If in two such laws neglected regions tended to bring doubt, by the apparent irreconcilability of facts with them, what better fate can be hoped for the law of natural selection if its foundation facts have been neglected and almost ignored? When there have been avowed Darwinians who have taken the ground that, so far as civilized men are concerned, the struggle for existence is entirely at an end, why should there not be trouble in explaining phenomena due chiefly or wholly to the action of disease? They have pointed to the fact that we have no longer any wild beasts to fight, that no animals now seriously contest with us our right to the food we eat, that our system of agriculture and our system of storage keep famine permanently from our doors, and that even the beggar can secure enough to lift him out of the brutal fight with hunger. But it can likewise be said of many animals in the wild state that they too can often get enough to eat without a serious hand-to-hand struggle for existence. Prof. W. E. Kellicot, while making a study of the common toad (*Bufo lentiginosus americanus*) found that in a colony of 450 individuals 13 had lost parts of toes in one or both feet; 2 had their feet crushed; 1 had old flesh wounds on its arm, thigh, and side of body; 4 had broken shanks that had healed short; 1 was minus a fore and hind foot with the stumps covered with heavy callosities; 1 had a broken clavicle with the ends projecting under the skin; 2 had each a small misshapen foot; 3 had one of their respective feet with 6, 4, and 3 toes; 5 had no gall-bladder; 1 had a ventricle deeply furrowed, ventrally; as if injured when very young. It thus happened that 8.75 per cent. of the entire colony were abnormal, yet able to secure a living under such handicap. It is thus evident that, even among amphibians, physical unfitness may be less crushing than disease and less likely to lead to favorable modifications.[7]



* Etiology still *sub judice*.

Prof. W. E. Kellicot, while making a study of the common toad (*Bufo lentiginosus americanus*) found that in a colony of 450 individuals 13 had lost parts of toes in one or both feet; 2 had their feet crushed; 1 had old flesh wounds on its arm, thigh, and side of body; 4 had broken shanks that had healed short; 1 was minus a fore and hind foot with the stumps covered with heavy callosities; 1 had a broken clavicle with the ends projecting under the skin; 2 had each a small misshapen foot; 3 had one of their respective feet with 6, 4, and 3 toes; 5 had no gall-bladder; 1 had a ventricle deeply furrowed, ventrally; as if injured when very young. It thus happened that 8.75 per cent. of the entire colony were abnormal, yet able to secure a living under such handicap. It is thus evident that, even among amphibians, physical unfitness may be less crushing than disease and less likely to lead to favorable modifications.[7]

The knowledge concerning that part of the Darwinian struggle to which Pasteur introduced us had been, in part, anticipated as early as 1863, by Rayer and Davaine, who had shown that there was some sort of connection between splenic fever and the anthrax bacillus. The demonstration, however, of the pathogenicity of the germ was not made until 1873 when Prof. Robert Koch succeeded in growing it outside of the living body. Following the work of Pasteur came a series of brilliant discoveries along similar lines and all supporting the view that infective disease in vertebrate and invertebrate animals is *a contest of cells with cells*—protozoan

and protophytan against metazoan—*for food*. It would be impractical, in a brief paper like this, to give a list of the hundreds of discoveries of disease germs that have been made among the lower animals and plants. There is not a single form of living thing in which, on careful examination, evidences of this contest have not been found. The few which, from a purely human standpoint, are now of the greatest importance, and all of which have been discovered within a period of less than thirty-five years, are already familiar to most medical men. In order to refresh the reader's memory, however, and to emphasize the part which they play in the battle for life the following short list is appended. It contains most of those known to attack human beings.

Year	Organism	Disease	Discoverer
1871	Amœba coli	Dysentery	Loesch.
1872	Bacillus septicus	Malignant œdema	Coze and Feltz.
1873	Spirochæte obermeyeri	Relapsing fever	Obermeyer.
1879	Micrococcus gonorrhœæ	Gonorrhea	Neisser.
1880	Trypanosoma evansi	Surra	Evans.
1880	Plasmodium malariæ	Malaria	Laveran.
1881	Diplococcus pneumonia	Croupous pneumonia	Pasteur, Sternberg, etc.
1882	Bacillus tuberculosus	Consumption, etc	Koch.
1882	Bacillus mallei	Glanders	Loeffler and Shutz.
1883	Bacillus pneumoniæ	Broncho pneumonia	Friedlander.
1883	Streptococcus erysipelatis	Erysipelas	Fehleisen.
1883	Bacillus typhosus	Typhoid fever	Eberth.
1884	Spirillum choleræ asiaticæ	Asiatic cholera	Koch.
1884	Bacillus diphtheriæ	Diphtheria	Klebs and Loeffler.
1887	Diplococcus intracellularis meningitidis	Meningitis	Weichselbaum and Jaeger.
1889	Bacillus tetanicus	Tetanus	Kitasato.
1892	Bacillus influenzæ	Influenza	Pfeiffer.
1893	Piroplasma babesii	Texas fever	Theobald Smith and Kilborne.
1894	Bacillus pestis bubonicæ	Plague	Kitasato and Yersin.
1901	Trypanosome gambiense	Sleeping sickness	Nepveu and Dutton.
1902	Bacillus dysenterica	Dysentery	Shiga.
1904	Unnamed protozoa (Cytoryctes variolæ ?)	Smallpox*	Councilman and Calkins.
1905	Cyclasterion scarlitinale	Scarlet fever*	Mallory.
1905	Treponema (Spirochæte) pallidum	Syphilis	Schaudinn and Hoffmann.

*Sub judice.

The largest number of pathogenic microorganisms discovered in the last half century, and proven to be pathogenic, since the time of Pasteur, have been found in insects, molluscs, fish, and amphibians. Huxley, many years ago, declared that "insects are wonderfully liable to the ravages of contagious diseases."[8] Prof. Minchin says that "There is perhaps no species of annalid, mollusc, arthropod, or vertebrate which is not liable to become the host of some kind of sporozoan parasite."[9] Prof. Calkins tells us that the pathogenic Protozoa "cause vast epidemics among silkworms, fish, and domestic animals, and have been the means of great economic loss, or through malignant epidemics, have terrorized whole communities and have brought about untold loss of life."[10] A writer in *Science* reports having made an actual count of the dead bodies of insects, and of parts thereof of sufficient size to be representative, which he collected from four square feet of meadow-land and an equal space of forest. He satisfied himself that these spaces fairly represented the average condition of the entire region. On the basis of his four square feet he calculated that there were "tangible remains of 240,030 departed insects on each acre of meadow and 488,925 on each acre of wood."[11] There was no indication of there having been anything in the nature of an epidemic and the figures, large as they may seem, can only represent a fraction of the true number of deaths. Wandering sarcophagous insects, that subsist upon such remains, must have consumed a large proportion. Insectivorous birds devoured multitudes of the living before serious sickness had an opportunity to scatter such remains over the ground. Few of us realize the enormous numbers of living things that become a prey to disease. We can see the great ravages of our "white plague" upon humanity but it never occurs to us that varieties of the same bacillus attack domestic animals, beasts, birds, and fish.[12] We note the tax on health and life of the diphtheria bacillus but it is only the human portion that we consider. The turkeys, chickens, pheasants, partridges, quail, Guinea fowls, and other birds may die from the same cause, and we know little or nothing about it.[13] To give due weight to disease as an important factor in Natural Selection all such cases must be considered. Nor should we forget even plants, for they, too, are sufferers, since "bacteria and parasitic fungi, which are themselves plants of a low order, are the cause of the bulk of the plant diseases."[14] Look where we will, into every nook and cranny of the biological world, and we will discover that "perfect health does not exist; living organisms are always in a state of unstable equilibrium, which finds its explanation and cause in the very conditions of life."[15]

From time to time virulent epidemics sweep over various parts of the earth. The struggle for existence is then intense and unless structural adaptations occur, or happen to be present in some of the exposed, the species is likely to perish. No type of living thing, and no particular region, is known to be exempt from the possibility of such visitations. Beasts, birds, fishes, and plants all, in turn, have to endure them. The story of the black death of the middle ages is common knowledge. The terrible havoc wrought by trypanosome diseases is coming to be equally well known among medical men. It is only a short time since the Island of Mauritius lost every horse by an epidemic of surra.[16] In 1904 the farmers of the Transvaal lost 15,000 cattle—one-third of all they had—from tick disease. The tsetse fly "renders thousands of square miles of Africa uninhabitable. No horses, cattle, nor dogs can venture, even for a day, into the so-called 'fly coun-

try.'"[17] Paleontologists inform us that there existed on this continent at one time a number of mammals similar to those now found in Africa. They "all died out with the great wave of death which swept off the camels, horses, and the giant South American sloths, just before or during the first advance of the Glacial Period."[18] When Columbus arrived no such animals existed here. In the neighborhood of Florrisant, Col., there is an extensive area of country which, like Pompeii and Herculaneum, was buried in volcanic ashes and lava, in Miocene times. From the pumice beds have been dug out numerous and interesting forms of animals that were then buried there. Prof. Cockerell has described one such find in these words: "Perhaps the most remarkable instance of this sort is afforded by the tsetse fly, Glossina. Scudder obtained from Florrisant an imperfect specimen of a large fly, which he regarded as representing a new genus and species. We were so fortunate as to secure a much better example, showing the long proboscis, and it was not difficult to recognize it as a veritable tsetse fly. The species, of course, is extinct but the genus is the same as that now confined to Africa, where it is dreaded as the disseminator of some of the most terrible diseases known. What part the existence of such flies may have played in the destruction of the tertiary mammalia we can only surmise, but it is not impossible that their influence was great. How it happened that they disappeared entirely from America and survived only on the Ethiopian continent is, of course, unknown."[19] That great destruction of plant life may be going on in our presence, with but few of us aware of it, is seen at present in the diseased condition of the chestnut and chiniquipin trees of the United States. Its fierceness can be inferred from an editorial note in *Torreya* which says: "It is well known that practically all of the chestnut trees in and about New York City have been killed within the past few years by the chestnut canker, *Diaporthe parasitica;* but the number of trees destroyed has been only very roughly estimated. Through the efforts, however, of Mr. J. J. Levison, arboriculturalist of the parks of Brooklyn, who has made a careful study of Forest Park, it is now known that 16,695 chestnut trees were killed in the 350 acres of woodland in this park alone."[20] That this is not the only instance of such wholesale destruction by plant disease is evident from the statement of Prof. E. S. Reynolds to the effect that "there are many diseases of trees, which, unless curbed, threaten the growing of forests,"[21] and of Prof. H. M. Richards who tells of great "loss through the destruction of crops from disease, losses which statistics show may amount to tens of millions annually" in the United States.[22]

The antiquity of parasitism is well known to most zoologists so that few or none of them would call in question Prof. Metchnikoff's statement to the effect that "Diseases in general and infective diseases in particular were developed on the earth at a very remote epoch. Far from being peculiar to man, animals, and the higher plants, they attack inferior forms and are widely distributed among unicellular organisms."[23] Within recent years considerable geological evidence has been discovered bearing directly on this point. Massee tells us that fossil plants have been found, within the tissues of which was evidence of their having been diseased when alive. In some specimens the pathogenic fungi were so well preserved that the structure of the perithecia with their conidia or spores was sufficiently perfect for study under the microscope. They were from "the lower carboniferous and permian rocks" and so must have been of a hoary antiquity millenniums before the first human being appeared upon the earth.[24] Fossil crinoids have been found in carboniferous limestone with parasitic Myzostomidia imbedded in their structures.[25] Bacteria have been detected in caprolites, fossil bones, and fossil tree-trunks "from the earliest geological ages" and "in forms closely resembling those now existing."[26] Fischer declares that "the fact that several species of fossil bacteria are known from the carboniferous and other periods shows that they are among the oldest inhabitants of the earth and were already widely distributed when the Tertiary Epoch and the evolution of warm-blooded creatures began."[27] Readers not familiar with geology may wish to know something about the probable number of years that lie between us and these early evidences of disease. Prof. Upham, in a very conservative manner, estimates that the facts in our possession give us reasons for believing that the Carboniferous Period existed "about four or five millions of years" ago.[28] The present habits of parasites, particularly of Protozoan parasites, and their distribution among their hosts, are just such as should be expected if they were descended from a long line of parasitic ancestors that extend back into the indefinite past. Their parasitism is inborn—hereditary—and gives many indications of having been so throughout geological ages. The methods of warfare of Protozoa against Protozoa differ but little from those they pursue against higher animal forms—the Metazoa. Their peculiar habits show as little change as is seen in the vertebra of a fish when compared with that of a man. They bear the characters of a common origin and indicate convergence at the beginnings of polycellular forms. In the case of *Amœba vespertilio* we find that the smaller Nucleophaga amœba, by taking up its abode in the nucleus of the former, causes that nucleus to degenerate and "a similar parasite in the macronucleus of *Paramecium caudatum* was described by Calkins as an intranuclear parasite similar to the intranuclear phase of the smallpox organism."[29] Metchnikoff has pointed out that "the most simple and the most primitive organisms have constantly to struggle for their existence, they give chase to living organisms in order to obtain food, and they defend themselves against other organisms in order that they may not become their prey. When the agressor in the struggle is much smaller than its adversary the result is that the former introduces itself into the body of the latter and destroys it by means of infections. In this case it takes up its abode in its adversary in order to absorb the contents of its host and to produce within it one or more generations."[30] Here we have all the essential features of an infection of an animal of the highest form of life. The successive steps from the preying upon an enemy to the making that enemy into a host are gradual, but the connecting links are all found among the primitive forms. In order to trace the methods by which the preying habit evolved into the intracellular parasitic habit we must go behind the first invasions of Metazoa. When we come to study the parasites that have adopted such a habit we discover that an entire zoological class has given itself over to this degraded form of life. The Sporozoa are "a class of Protozoa which, without any exceptions, are parasitic and thus infest all animal forms from Protozoa to man."[31] Another author describes them as

"a group of exclusively parasitic Protozoa, of very widespread occurrence, infesting the internal organs or tissues of animals belonging to almost all classes and orders of cœlomate Metazoa."[32] This condition is one of great significance, and one which the reader should try to picture, in his imagination, as a whole. Consider the class Sporozoa as a genealogical tree, the diverging large branches of which constitute its orders, the sub-branches the genera, and the subdivisions of these sub-branches the species. All of the smallest sub-branches are unlike each other, but as they converge toward the trunk the linking resemblances become apparent. Considered as common kindred, and remembering the immensity of time needed to produce such changes, what can be the meaning of the fact that *they are all,* without a solitary exception, parasites? So completely dependent upon parasitism are they that not one of the multitudes of distinct forms could continue to live without its special hosts. The whole structure of their organization is adapted to a parasitic life and to no other, except in their brief resting condition as spores. What could have been the origin of this state of affairs? Where, when, and how did this abject dependence upon parasitism originate? It could not have begun within the lifetime of any individual among them for they are all alike parasitic. Vast as is the time which probably covers the origin of the various species of a genus it could not have begun within this time for all of the species are obligatory parasites. It could not have begun within the life history of any one genus for all of its kindred genera are incapable of any other than a parasitic life. It could not have begun during the development of any one of the orders for every order is unalterably riveted to parasitism. Look at the facts in any way we choose and the conclusion is forced upon us that the existing parasitism of the Sporozoa is as old, or older, than the class. The fact that related branches of other classes are parasitic bears out the latter conclusion. For many millions of years disease must have existed much as it does to-day and all available facts indicate that it began before there was even as high an animal on the earth as a jelly-fish. This conclusion is further confirmed by the distribution of the various branches. Sporozoan parasites infest all kinds of worms, insects, crustaceans, molluscs, fishes, amphibians, reptiles, birds, beasts, and men, and do so in a way that is far from being fortuitous. The general rule is that "each species of Sporozoa is parasitic on a particular species of hosts, or on a limited number of allied species."[33] While there may be overlappings from one kind of host to another, as when mosquitos and men, tsetse flies and cattle, harbor the same species, and when birds, beasts, monkeys, and men harbor forms of varying degrees of kinship, in the great bulk of cases there is a regularity about the distribution. The gregarines "are confined for the most part to invertebrate hosts," the Hæmosporidia "are parasitic usually upon the red blood-corpuscles, sometimes also upon the cells, of Vertebrata," the Phænocystes are preeminently parasites of Vertebrata and especially of fishes," and the Sarcosporidia "with the rarest exceptions are parasites of the striped muscles of warm-blooded vertebrates, birds, and mammals."[34] This limiting of special kinds of Sporozoa to special kinds of hosts and of kindred species of Sporozoa to allied species of hosts, seems to imply parallel evolution of both. The implication, too, is confirmed by the limiting of specific parasites to special host organs. Calkins tells us that, "one group lives in the digestive tract and the cavities of the body (*Gregarinida*); another in the cells of the digestive organs (*Coccidiida*); another in the muscle cells and lymph surrounding them (*Myxesporidiida* and *Sarcosporidiida*); and still another in the blood-plasm (*Hæmosporidiida*)."[35] Some have a preference for the spleen, some for the kidneys, some for the gall-bladder, some for the liver, some for the ovaries, and some for the testes. Those that prefer the testes avoid the ovaries and those that take to the ovaries are never found in the testes. This apparent choice, on the part of such lowly one-celled organisms, is one of the most peculiar of nature's strange phenomena. We can hazard but two theories as to its cause. Either it is a chemical attraction exerted by the organ upon the parasite or it is the presence in the circulation of some desirable substance that causes the latter to hunt for the source of supply and to find it in that organ. As different organisms have different organs as choice—if choice we are permitted to call it for lack of a better word—it follows that we are here dealing with a series of adaptations that the Darwinian can only interpret as survived fitnesses. The special organs or tissues have come to be a life or death necessity for the parasite. It cannot live without that special organ. Other organs have placed some opposing barrier against it. All of its kin have perished that failed to acquire this one-organ habit. It, and its kind, have ceased to be able to contest with other organs of the body successfully. The food that other organs supplied has become, what we may, for lack of a better word, call, distasteful. It is to the parasite, evidently unsuitable, poisonous, as it were. A similar condition is seen between plants and the higher animals. The food of one animal is disagreeable or poisonous to another as a result of a similar selection. One kind must have the poisonous Solanacea to live upon while another must have clover or grass. One loves the bitter leaves of the oak while another prefers the succulent leaves of a cabbage.

A glance at the accompanying diagram will show, in a rough way, that many a battle must have been fought between hosts and parasites during the long geological ages of their evolutionary history—their phylogeny. Only a comparative few, of the many kinds of Protozoan parasites, have held their own in the long ordeal and been able to mount up to man and make him their host. The great bulk of them have been left behind in frogs and fish, insects and worms, turtles and lizards. Many of them have been so specialized that they can live only in a few kinds of the higher forms. (The specialization is shown by the scattered positions of the lower-case, or small letters of the diagram, as found at the ends of the tree branches.) A parasite that is capable of living only within worms of various kinds finds no suitable food in other kinds or else such food as it does find is poisonous to it, or there is some sort of barrier that makes life for it impossible there. We must not lose sight of the fact that all this control of parasites which compels one to stick to the liver, another to the kidney, another to the spleen, another to the pancreas, another to the ovaries, another to the testes, etc., means ages of struggle to the death, and what is still more important, at present, means that all of the organs of the body have been compelled to change their chemical composition, structure, or both, in order to gain their immunity. The parasites that have acquired a composition that enabled them

to subdue one organ, and live there in relative comfort, have been the kinds of parasites that have caused readjustments and readaptations innumerable, in all other organs prior to the evolution of the higher forms of living animals from these lower forms. At the beginning of the disease struggle between the lower forms—Protozoa—and the higher forms of animals—Metazoa—there could have been no choice of organs since there were no such organs. One part of the host was as acceptable for food as another. As the selection of organs, as choice locations for parasites, begins low down in the scale of animal life, it is evident that such organs were subjected, at a very early period, to these attacks and the chemical and structural natures of the same had to undergo modification near to, or at, their beginnings. We have here to face exactly the same kinds of problems of adaptations as have hitherto held the field regarding the higher plants and animals. As the structures and shapes of flowers have been moulded into accommodation for insects, in order to facilitate cross-fertilization, so must the internal organs of all the higher forms of animals have had their structures and forms moulded into opposition to parasitism. There is not a part or particle of the body that has not needed some sort of immunity against attack. That all parts have received some kind of immunity is proved by our being here. That it is not all-sufficient is seen when we know that every check upon the parasite often—but not always—means a counter check on its part in order to overcome our protection. Both parasite and host have adopted a number of ways of overcoming each other's attacks. The two chief ones are protective coverings and secretion of poisons, and both of these are common to both parasite and host. In order to overcome each other's protective coverings special enzymes must be secreted that are capable of dissolving such coverings. In order to overcome each other's poisons antibodies are required to neutralize or hold them in abeyance. To be able to enter a given kind of cell the parasite must have the power of dissolving the cell-wall, when it is incapable of mechanically rupturing it. The organs that cannot attack have cell-structures it is unable to pierce or secrete poisons it cannot neutralize. The fact that we are immune to so many kinds of parasites shows that we have gained structural and poisonous protection, through milleniums of struggle, against their progenitors and kindred. They have failed to keep up their adaptations against us. At the beginnings of Metazoan life there could have been no specially protected parts and every form must have been vulnerable at all or most points. Then the parasitic protozoa had common proclivities. Now they have changed into many forms with many habits. The relations of the two to each other, during the entire period of the long war between them, is given in the accompanying diagrammatic sketch, which is, necessarily, imperfect. In order to facilitate medical men in tracing the connections between the pathogenic forms that are at present creating so much interest, it became imperative that the top of the evolutionary trees be elongated and so distorted. The true space from mammals to men would scarcely fill a line. The spaces between worms and reptiles, covering many millions of years, had to be shortened materially, and those from reptiles to men, covering a much shorter period of time, lengthened, in order to accommodate the figure to a satisfactory size and to emphasize the points of special interest to physicians. The list of human and mammalian diseases, at the top, includes all that are at present of prime importance to the profession. This, I believe, is the first time that these have been put into a shape in which it is easy to see, at a glance, exactly how all of these diseases are related to each other. By passing the eye from the disease names down the branch to the trunk and up again to other disease names their exact relationship is seen. The three trees might have been drawn as three huge branches from a common protozoan trunk, but it was deemed more satisfactory to show the kinship connection of the three classes by uniting them by their roots. With this diagram before him the doctor will get a better idea of the part protozoology now plays in medicine than he could from any medical work upon the subject, unless he is prepared to sit down and give it a lot of hard study. Those willing to try and master some of the details will find the following key to the diagram of service:

MASTIGOPHORA. (Class.)
- *FLAGELLATA. (Sub-class.)
  - 1. Monadidæ. (Order.)
    - *A.* Protomastagina. (Sub-order.)
      c. Critbida, *d.* Herpetomonas, *e. f.* Trypanoplasma, *g.* Trypanosoma, *h.* Spirochæta, (*h*) Treponema, *i.* Leishmannia. (Genera.)
    - *B.* Polymastagina. (Sub-order.)
      j. Trichomastix, *k.* Trichomonas, *l.* Lamblia, *m.* Trichonympha, *n.* Lophomonas. (Genera.)

SPOROZOA. (Class.)
- †TELESPORIDIA. (Sub-class.)
  - 1. Gregarinidia. (Order.)
    - *A.* Acephalina. (Sub-order.)
      a. Monocystis. (Genus.)
    - *B.* Cephalina. (Sub-order.)
      b. Aggragata, *c.* Porospora, *d.* Gregarina, *e.* Gamocystis, *f.* Eirmocystis. (Genera.)
  - 2. Coccidiida. (Order.)
    - *C.* Polysporocystidia. (Family.)
      g. Klossia, *h.* Diosporia, *i.* Adelea. (Genera.)
    - *D.* Disporocystidia. (Family.)
      j. Isospora, *k.* Diplospora, *l.* Cyclospora. (Genera.)
    - *E.* Tetrasporocystidia. (Family.)
      m. Crystallospora, *n.* Coccidium. (Genera.)
  - 3. Hæmosporidiida. (Order.)
    - *F.* Hæmosporea. (Sub-order.)
      o. Hæmogregarina. (Genus.)
    - *G.* Acystosporea. (Sub-order.)
      p. Halteridium, *q.* Plasmodium, *r.* Piroplasma, (Genera.)
- *NEOSPORIDIA. (Sub-class.)
  - 4. Sarcosporidia. (Order.)
    a. Sarcocystis. (Genus.)
  - 5. Haplosporidia. (Order.)
    b. Cytoryctes, *c.* Rhinosporidium, *d.* Haplosporidium. (Genera.)
  - 6. Myxosporidia. (Order.)
    - *H.* Myxobolidæ. (Family.)
      e. Myxobolus, *f.* Henneguya. (Genera.)
    - *I.* Chloromyxidæ. (Family.)
      g. Chloromyxum. (Genus.)
    - *J.* Myxidiidæ. (Family.)
      h. Myxisoma, *i.* Myxidium, *j.* Leptotheca, *k.* Ceratomyxa, *l.* Myxosomo, (Genera.)
  - 7. Microsporidia. (Order.)
    - *K.* Polysporogenæ. (Section.)
      m. Glugea, *n.* Myxocystis. (Genera.)
    - *L.* Oligosporogenia. (Section.)
      o. Gurleya. (Genus.)

SARCODYNIA. (Class.)
- RHIZOPODA. (Sub-class.)
  - Amœbida. (Order.)
    a. Amœba. (Genus.) [36]

Although Darwin was entirely unconscious of the fact that disease is an important part of the biotic fight for food, and therefore an essential part of his great theory, he seems to have had a vague perception of its taking a place of no mean utility in the fight. In his chapter upon "The Struggle for Existence" he ends his argument with the remarkable statement that "the vigorous, the healthy, and the happy survive and multiply."[37] He evidently looked upon vigor, health and happiness as the supreme surviving benefits of the struggle which he had just been depicting. If this is so, then lack of vigor, disease, and unhappiness were the conditions out of which the survivals must have most frequently occurred. But lack of vigor is but a symptom of disease and unhappiness is usually a consequence of its presence. The supreme feature of survival and of fitness would thus appear to be due

to a triumph over disease. A glance at nature will show the truth of this. If a herd of deer is fleeing from a pack of wolves, those first overtaken and killed, other things being equal, will be the ailing, and in other successive flights from wolves the new victims will be chosen in accord with the seriousness of their ailments. If severe weather has to be faced by the herd the first to perish will be the very sickly, and as the weather becomes more and more severe those chosen for destruction are likely to die in the order of the severity of their respective diseases. If famine overtakes them, other things again being equal, the worst afflicted perish first and the rest in the ratio-order of their afflictions. In flood, in tempest, in forest or prairie fire, in contests with enemies or with their own kind, in fact, in all adverse conditions of life, death chooses its victims in the order of the severity of the diseases that happen to afflict them. What is true of deer is likewise true of every living creature. The decisive factor that runs through every struggle wherein other things are equal is disease. There is no other factor so universally present. Only organisms that have gained a high degree of resistance to disease germs are capable of maintaining their own in any severe contest, no matter what its nature may be. The first requisite is health, and health is only possible among organisms the progenitors of which have triumphed over disease and left them a proper heritage. Disease tips the scales for or against survival in almost every trying condition. Tempests of such severity as to defy the boundary line of disease leave no survivals and cannot modify the race. Famines that bring as much destruction upon the healthy as upon the sickly have no selective value and leave no fittest to survive. Great earthquakes, tidal waves, with other universal and merciless exterminators, take no part in natural selection because they do not select. Cold that is so rigorous as to defy the endurance of the most healthy can add no new adaptations to heredity. The survival of fitness only occurs at the border-line of endurance—the line between health and death. The survivors are those that escape death in the presence of a persisting danger. They are those that have become modified in a way to resist strain.

Before it was perceived that disease is an undisputable battlefield of the true Darwinian struggle for existence, the tremendous part which it takes in ridding the earth of weaklings and causing the survival of health was all credited to the environment and its dead physical forces. Climatic influences and other predisposing causes of disease were imagined to be the prime and efficient causes. Naturally this view still holds its place in the lay mind, so that many zoologists and botanists are still held in the thraldom of this old superstition. It is almost impossible to overestimate the influence for evil that it is now having upon biological science. It tends to divide evolutionists into warring factions over problems that would never have arisen if they had been long ago made to see the Darwinian nature of disease. In a sort of way they probably all see a connection between Darwinism and disease, but it is, as yet, so vague that there is no mental fruition from it. They fail to assimilate them in their thoughts. Take, for instance, the following statement by a leading zoologist who seems to be still controlled by the old way of thinking upon this subject. He says: "I have long been a believer, in common with my fellow systematists, in the evolution of species and races by environment, which, of course, includes evolution by isolation. This seems far more rational than evolution by natural selection, as this process was originally defined. But since the inefficiency of natural selection, pure and simple, to produce the results formerly attributed to it became evident, the significance of the term has been expanded to embrace evolution through climatic influences, including also the factor of isolation."[38] We see here the distinct mental trend of the non-medical mind on a problem similar to one over which physicians wrestled a generation ago. Just as the doctors sought to make predisposing causes responsible for the symptoms of disease so now the zoologists seek to repeat that error in evolution. The apparent inefficiency of natural selection complained of is due to his own inability to see natural selection, pure and simple, doing the very things he declares it does not do. Evolution through climatic influences, including also the factor of isolation, is neither more nor less than evolution through disease. Climate and isolation predispose to disease and thereby predispose to variation, but neither is an efficient cause in the absence of disease. This truth is being assimilated by ecologists, among the botanists, probably because it is their function to study plant diseases, while it is but a small part of the average zoologist's duty to understand the nature of animal diseases, or their relation to evolution. Prof. Clements tells us that, "Abnormal adjustment occurs in those plants that migrate into a new or different habitat, or those whose habitat is seriously changed. It is characterized, as a rule, by profound disturbance of function, though the latter depends upon the intensity of the change. The most familiar cases of abnormal response are due to biotic factors, particularly parasitic fungi and insects."[39] Here we have a distinct acknowledgment of the part played by disease in evolution and of its being a struggle for food between the plants and their biotic enemies. He also shows us that the isolation of new habitats leads to disease. There is here no vague references to environment and climate, as he shows us exactly what features of each lead to the changes. Prof. H. Bolley, another ecologist, says: "For a number of years I have attempted to hasten the survival of the fittest, or of the unlike, through the development of or heightening of the action of plant disease for the purpose of eliminating the weak or unfit. * * * The method has given marked results when applied to wheat *versus* wheat rust; wheat *versus* wheat smut; flax *versus* flax rust; flax *versus* flax wilt; potatos *versus* scab and blight. My observations along these lines have been such that I have no fear but that the future will find me right in the assertion (1) that mutants may be so insignificant and numerous as to be unrecognizable and thus fall directly into the class called by de Vries 'fluctuating variations'; or (2) that they may be induced in a mixture of a great number of variations of a species at one and the same time because of the same environmental causes; or (3) that in some cases 'fluctuating variations' are of such nature and worth as to allow results to be obtained in mass breeding of as great importance as any that may be hoped to be obtained by looking for a single mutating type evolved through the method of de Vries."[40] The professor distinctly states that his variations that breed true from their seeds (mutations) are most likely the direct products of the diseases he uses in making the fit survive, and, as we will soon see, this is, probably, just what he is causing to happen. The variations

that do not breed true (fluctuating variations) are such as have not been impressed upon the seeds. They are variations of the plant itself (somatic variations) that have left no impress upon the seed. It is important to note the fact that this method of treating the plants has given numerous mutations, but, so far as amount of change is concerned, of insignificant value in some instances. He has shown that Prof. C. B. Davenport was right when he declared that "the abnormal is, paradoxical as it may sound, the important for evolution."[41] The fact is that it is impossible to think of any scheme by which evolution could be brought about that is not due to the introduction of the abnormal. All the experiments that have yet been made, in trying to solve the problems of evolution, have been just such as would favor disease. They all introduce abnormal conditions for the plant or animal experimented upon. Every condition lying between a fish and a mammal, or a fish and a bird, is abnormal to the fish, and to every modification which it might be supposed to assume in mounting mammal-ward or bird-ward. The conditions of life in every high form are abnormal to the earlier forms from which they may be supposed to have evolved phylogenetically. The adaptations which the high forms display are fitnesses to conditions of prior abnormality. As all biotic responses to abnormal conditions are symptoms of disease, then all modifications of the organism to new, i. e. abnormal, conditions are pathological products. The body in its war against the abnormal introduces the new adaptations or adjustments. But bodily adaptations cannot be directly transmitted by heredity. Only when the germ-plasm has had to respond in a similar manner can progeny acquire any adaptation that may be made by the body. It is quite evident to every medical man that "the germ-plasm is not isolated anatomically or physiologically, and that the germ cells, so far as is known, possess the same property of response as do other cells or whole individuals,"[42] so that anything that affects the body as a whole must affect the germ-plasm in at least a proportional degree. Indeed, there are reasons for suspecting that germ and sperm cells are somewhat more sensitive to certain kinds of stimulating substances, that happen to reach the circulation, than are some of the other cells of the body. Prof. H. B. Ward in an address as chairman of Section C of the American Association for the Advancement of Science, declared that, "It has been frequently noted that parasitic infestation tends to retard the development of the host organism. In fact, it does not hinder the general growth of the host strikingly, but arrests primarily its sexual development. This has been especially investigated by Alfred Giard, who denominates the phenomenon parasitic castration and defines it as the sum total of modifications produced by a parasite on the reproductive apparatus. The phenomena appears to be widespread, instances being found in all branches of the animal kingdom and as a result of the most varied sort of parasites."[43] Here the poisonous products of the parasites seem to affect the germ-plasm more profoundly than the soma-plasm. The degree of effect must, of course, vary with the amount of the toxic agent so that we can easily infer that there are many results between the absence of all effect and the presence of the optimum castration. The character of such effects can now be clearly inferred from some of the experimental results obtained by both botanists and zoologists. Prof. MacDougall, experimenting with plants, has, up to the present time, reported the most startling results. Taking different plants belonging to the genera Raimannia, Oenothera, and Cereus, and subjecting the germplasm to dilute, but slightly toxic, solutions of calcium nitrate, potassium iodide, zinc sulphate,, or methyl blue, he saved the seeds from his treated ovaries and grew plants from them for a series of years. In this way he discovered that he was able to produce plants having qualities quite unlike those of their parents, qualities that were transmissible through as many generations as he has been able to test them, and qualities unknown to kindred forms.[44] In other words, he has created new species of plants similar to the mutants of Prof. de Vries. Indeed, he took the de Vries plant—the evening primrose—and by the aid of injections of solutions of zinc sulphate into the ovaries, produced forms with new qualities that, at last report, had bred true for three successive generations. In the case of de Vries's plants it is quite likely that transplantation from America to Holland had mildly poisoned their germ-plasm, owing to soil poisons or parasite poisons in the sap, as in MacDougall's experiments. If chemical substances, by action on the cell chromosomes, can produce such results, why may not the toxins of disease have been doing the same thing during the countless milleniums of geological time? That the nature of the stimulation is not the essential cause is seen in the fact that many kinds of poisons can accomplish similar results. Nor are such results only possible for poisons. The stimulation of radioactive substances when carried near to the disease point give us similar effects. Prof C. Stewart Gager has put this to the test and finds that "when the pollen or the ovary is exposed before pollination, or the ovary after fertilization, the resulting seeds produce plants profoundly different in the first generation from that normal for the species."[45] It seems that radioactive substances produce these results through disturbing the normal processes of cell-division, for "exposure to the rays also induces marked irregularities of mitosis. This is shown, among other ways, by the failure of some of the chromosomes to take part in the organization of the daughter nuclei. Usually such chromosomes organize smaller, nuclear-like structures within the daughter cells. In one instance they were observed to be undergoing an independent karykinesis at one side of the main mitotic figure. Interesting possibilities are here suggested along the line of experimental mutation. Experiments like those described in this paper have been many times repeated with confirmatory results, and seem amply to justify the general conclusion, earlier stated that radium rays are a stimulus to plant activities."[46] That poisons act on mitoses in a similar manner is evident from Prof. Wilson's statement that "Under certain circumstances the delicate mechanism of cell-division may be deranged, and so give rise to various forms of pathological mitoses. Such a miscarriage may be artificially produced, as Hertwig, Galeotti, and others have shown, by treating the dividing cells with poisons and other chemical substances (quinine, chloral, nicotine, potassium iodide, etc.)."[47] If we turn from the consideration of plant experiments to those of animals, we again discover that poisons produce results quite in agreement with those already given. Mr. C. R. Stockard has repeatedly, and *at will,* produced from the eggs of the fish, *Fundulus heteroclitus,* hundreds of specimens in which, instead of two eyes, one on each

side of the head, he got one eye in the center of the same. He tells us that "the cyclopean individuals appear to be as active as the normal and their ability to live would seem to depend only upon the possibility of their obtaining food."[48] All that is needed, in order to produce such strange results, is to add a definite amount of magnesium chloride to the water in which the eggs develop. It is evident from this that "changes in the relative positions of parts which would be absolutely impossible in the adult may be readily accomplished in the unsegmented egg, as is shown by cases of inverse symmetry."[49] The nearer we get to the germ-plasm the easier it is to produce changes in adult forms that arise from such plasm. A little rill, at the source of a river, is easier to divert from its regular course than is the mighty river that started from this rill. In the experiments of Prof. W. L. Tower, on Chrysomelid beetles of the genus Leptinotarsa (Colorado potato bugs), "it is shown that there are variations which are inheritable and others that are not; and * * * it is further shown that the heritable variations as far as discovered arose in the germ-plasm, the non-inheritable during development in the soma. Further, the experiments * * * show that heritable variations arise as the response to stimuli applied to the germ-plasm. These responses, moreover, follow exactly the law of error in their distribution around the normal mean. I maintain, therefore, that *all organic variations are responses to stimuli*, and are not due to inherent tendencies or latencies."[50] The conditions tried by Prof. Tower on these beetles were those of abnormal temperatures, abnormal humidity, abnormal food supplies, and abnormal environments. By the use of these abnormal conditions pathological responses occurred that became heriditable. The only stimulus that could reach the germ-plasm would be that borne to it by the circulation. Such beetles are the common hosts of protozoa and of bacteria. The increasing discomfort of increased temperature and increased humidity would lessen the resistance of the beetles to the parasites. This would favor the multiplication of the parasites within their hosts. Toxins would be thereby caused to increase to a quantity that would stimulate abnormal mitotic changes and demand readjustments within the germ cells. The poisons of perverted metabolism, due to the abnormal conditions, might also act in this way. It thus appears that the experiments of Towers, Gager, MacDougall, and Stockard, all, tell the same kind of a story, viz., that structural changes are a resultant of the germ-plasm stimulation when that stimulation reaches toward the optimum power of endurance—the point of disease production. We know of no experiments in which the problems of evolution have been under investigation in which abnormal conditions have not been resorted to. We can conceive of no evolutionary experiments that would help us to any knowledge of the subject that would not place the organism in abnormal conditions. We cannot imagine a means by which nature could have wrought existing results save through conditions favorable to disease. When we study the distribution of parasites, in time and place, we find that these are just such as they ought to be if such parasites had been the source of germ-plasm stimulation like that required to give us a biological world such as we have. It thus seems probable that what we have hitherto deemed altogether a thing accursed—disease—may yet be proved to be a blessing in disguise. It can truly be said of all our race that "these are they that came up through great tribulation" but, without such tribulation, there could have been no such perfection of beauty and of form as we find upon the earth at present.

RENAL TUBERCULOSIS AND ITS SURGICAL TREATMENT.*

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

Tuberculous infection of the kidney has been thought to take place by ascending infection from the bladder, a much-mooted question, in which case one is dealing with a secondary renal tuberculosis, one or both kidneys being involved. In all probability, however, the bacillus reaches the kidney by way of the blood and involves the glomerulæ, or it may remain in the intercanalicular connective tissue. The cortical zone appears to be the point of predeliction for the attack of the bacillus.

When the kidney has become infected, tuberculous granulations develop in variable quantity, be-

*Presented to the Urological Society of Belgium, May, 1909.

ing either disseminated throughout the kidney substance or else collected in masses which by their fusion form tuberculomato of variable dimensions. The kidney will be found riddled with caseous masses, forming large rounded foci in the parenchyma, often projecting on the surface of the organ. This is the infiltrating form of the affection. The renal pelvis may remain intact.

The caseous masses finally soften and transform into cavities. The medullary layer of the kidney, the pyramids and their intertices will be found filled with irregular cavities with indurated and ragged borders, containing dry or soft caseous matter or a yellowish purulent fluid, which may make its way outwards by way of the calices, renal pelvis and ureter. This may be termed tuberculous pyelonephritis.

The cavities are in the first place isolated and localized in the lower portion of the kidney and are separated by walls which finally disappear, giving rise to one large cavity. In this case the kidney is more or less completely destroyed, the walls of the cavity being formed by the renal capsule. By the passage of the tubercluous matter the ureter in turn becomes involved. It may become temporarily or permanently obstructed, this giving rise to pyelonephritis with distention and symptoms of infection from retention.

If the ureter becomes permanently obstructed the kidney will in turn become completely disorganized. Or, on the other hand, obstruction of the ureter may result in a tuberculous hydro-nephrosis which in no way differs from an ordinary aspetic dilatation of the kidney. In some few cases the kidney undergoes a total caseous necrosis. These various pathologic types of chronic renal tuberculosis—the only ones of surgical interest—may be found combined in one kidney.

Complete involvement of a kidney does not of necessity always take place because the lesion may be limited, with a tendency towards cicatrization. The granulations undergo calcification, resulting in the development of a true renal calculus, whose nucleus contains the specific bacillus. The walls of the cavities granulate, filling up the loss of substance, and at the same time there is a peripheral atrophy of the parenchyma.

Primary tuberculosis when developing in the depths of the parenchyma, thus protected from mixed infection, should offer greater opportunities for spontaneous cure than secondary tuberculosis which involves the kidney at the time that it has been invaded by pyogenic bacteria. This question, however, is not settled, but it would appear that the duration of primary tuberculosis is much longer than the secondary form. For that matter, this diagnostic precision as to the starting point of renal tuberculosis is only of relative value from the operative standpoint, but I may here say that in my opinion primary renal tuberculosis of a single kidney is far from being infrequent. A single kidney when infected by the specific bacillus producing its special lesions will make itself evident symptomatically by renal pain or hematuria.

According to the length of duration of the process, the kidney may be found more or less increased in size, but occasionally it is artophied. It may also retain its normal size, but usually it forms an appreciable tumor. More or less marked bossae or even cavities may be found on its surface and not infrequently it will be slightly prolapsed. In cases of long standing, there is most always a perinephritis, while the envelopes of the kidney form a limiting zone isolating the focus from the remainder of the organism. The renal capsule can only with difficulty be detached and is thickened, ulcerated and indurated. The perirenal fat is very vascular and hard and contributes partially to the formation of the renal tumor when perhaps the kidney itself is not increased in size. The organ may be in reality atrophied and buried in the indurated fat. This perirenal tumor, which usually is most marked in the neighborhood of the renal pelvis, may continue down along the ureter. In other cases the fatty capsule is involved by the tuberculous process, giving rise to abscess formation when a renal cavity has opened into the perirenal fat. Very large abscesses, extending up under the liver or diaphragm, or downwards along the psoas have been encountered. When these are opened an irregular pocket is found, composed of numerous diverticula, containing purulent or serous fluid having a fetid, urinary odor. After the pocket has been emptied the walls are with difficulty removed on account of their great hardness and intimate adhesion with the surrounding structures.

In the region of the hilum an irregular tumor will be found, very adherent and composed of lymph-nodes in which a tuberculous process has developed. In consequence of the perirenal sclerosis, there is a retraction of the organs contained in it, particularly of the renal vein, which consequently draws the vena cava or even the aorta towards the diseased kidney. The perinephritis may also contract adhesions with the colon, peritoneum or small intestine and when these exist on the right side they render the operation extremely difficult and dangerous. A diagnosis of this condition of affairs is impossible and can only be suspected.

In the primary type of renal tuberculosis the ureter is often involved, and nearly always so in the secondary type. It is increased in size, its walls infiltrated, thickened and sclerotic, while the mucosa presents ulcerations and strictures. Its lumen may thus become permanently or temporarily obliterated.

The bladder may present tuberculous lesions in the neighborhood of the ureteric orifice in the form of granulations or ulcerations, but what should be particularly studied is the condition of the other kidney and the genital apparatus.

From the statistics of Roberts, Dickenson, Morris, and Guyon, unilateral renal tuberculosis is encountered about once out of every three cases. When it is bilateral, one kidney is usually more diseased than its fellow. Of course, when the second kidney has become involved, it is a contraindication for surgical interference. On the other hand, the second kidney may not be tuberculous, but presents a pyelonephritis or an amyloid degeneration, both of which contraindicate operation. Of course, a compensatory hypertrophy is favorable, and nephrectomy of the diseased kidney may be undertaken.

The genital apparatus must be carefully investigated because it is frequently involved. The prostate, testicles, epididymis, and vas deferens must be carefully explored. In the female, however, the genital apparatus is rarely involved on account of its complete dissociation with the urinary tract.

In surgical interference for tuberculosis of the kidney one must be guided by the symptoms presented. These are hematuria, pain in the renal region and pyelonephritis. Hematuria is often the first symptom and is to be considered in the same light as

hemoptysis occurring in pulmonary tuberculosis. It would seem that this symptom is due to renal congestion and is of considerable value in diagnosis of renal tuberculosis. It often appears spontaneously without any apparent cause in a patient who has been urinating normally. This hematuria is not influenced by movement, and rest will not cause it to cease as in hemorrhage from renal calculus. There may be absolutely no pain in the kidney. The urine may be only slightly tinted with blood or it may be dark red, while in some cases the loss of blood is so slight that it can only be demonstrated with the microscope. In some cases the hematuria may be severe, occurring irregularly. It may last several days or a week or two and then disappear without any cause. It may give rise to nephritic colic when a blood clot obstructs the ureter. The hematuria is usually present when the tubercles are developing in the renal cortex, which is almost exclusively composed of vessels.* The following case is an excellent example of initial hematuria in renal tuberculosis:

A strong and well-built man, thirty-two years of age, consulted me for loss of blood occurring after micturition. It occurred only once at the end of micturition, the patient stating that the amount might have been about a teaspoonful of practically clear blood. Other than a feeling of lassitude the patient presented no other symptoms. The urine voided in my presence was uniformally cloudy, containing minute white flakes. Cystoscopic examination was made by Dr. John Cunningham with the following results. The bladder was normal, likewise the left ureteric orifice, but the right orifice was somewhat swollen and hyperemic. The urine from the left kidney was found perfectly normal, that obtained from the right was loaded with bacilli of tuberculosis. This was proved by inoculation of guinea pigs, three of which died within a few weeks with marked peritoneal tuberculosis. I advised immediate nephrectomy, which the patient refused because he considered himself too well to be operated on. This man was under my observation for eighteen months, his condition remaining absolutely the same. The urine did not change in nature and no evidence of further infection occurred in any other organ. At the end of eighteen months he finally accepted nephrectomy. The kidney was found tuberculous, particularly in the cortex, the renal pelvis only presenting a mild degree of catarrhal changes. This was done eight months ago and the patient now enjoys perfect health.

The hematuria of renal tuberculosis may be mistaken for one occurring from prostatic hypertrophy, or some urethral growth, particularly when it occurs as in the above mentioned case. The hematuria of vesical calculus occurs at the end of micturition after walking or riding over a rough road, but cystoscopic examination will clear up the diagnosis. In cases of tuberculous cystitis the pain in the bladder will be intense and early hematuria occurs, the latter having the same character as that coming from the kidney. The diagnosis will be made easy if signs of beginning tuberculosis are found in the prostate, epididymis, and seminal vesicles. The cystoscope will remove all doubts.

Hematuria occurring in a patient presenting tuberculous lesions of some other portion of the genital-urinary apparatus, and then developing persistent lumbar pain is symptomatic of renal involvement from ascending infection.

The diagnosis of hematuria symptomatic of a renal neoplasm is more difficult. In this case it is often early in occurrence, and sometimes the only symptom. Hematuria is often the only symptom of a neoplasm of the bladder, but in this case the hemorrhages occur at long intervals, and the elongated, wormlike clots that come from the ureter are never encountered. Here again the cystoscope is the surest means of diagnosis.

Hematuria from renal lithiasis is more prone to occur after fatigue, walking or rough riding, and, like the pain, when it is present, disappears with rest.

To the early symptoms of renal tuberculosis, such as simple polyuria and frequency of micturition, the patient may complain of lumbar pain. Cases of renal tuberculosis are met with where repeated nephritic colic is complained of without any hematuria or purulent urine. Its characters vary greatly. Some patients may complain simply of a transitory ache in the back, while others state that it is very sharp and either intermittent or continued. Walking or pressure over the kidney do not appear to have much influence on the pain. In the female, the paroxysms have a tendency to occur at the menstrual periods. When there is renal retention, the pain will cease after the renal pelvis has emptied itself of the pus, epithelia, and caseous masses which have caused the obstruction.

I would particularly warn physicians not to mistake this pain for lumbago, more particularly so as it may occur suddenly after taking cold or a strain. It will also disappear by rest. Pain due to renal calculus is more acute and shoots down along the ureter; riding and walking increase it while it improves by rest. The indefinite pain complained of in the early development of renal growths is certainly hard to diagnosticate. If persistent pain in the lumbar region occurs in a phthisical subject presenting polyuria and albumen, renal tuberculosis should be suspected. At the same time that the pain occurs palpation may occasionally reveal an enlarged kidney which may be movable or not.

If the renal tumor felt is due to a pyonephrosis resulting from an obstruction in the ureter, thus producing retention, there will be a sudden enlargement in the lumbar region, while this will disappear when diuresis has become established. At a more advanced stage in the process the obstruction may be caused by phosphatic concretions becoming lodged in the ureter, likewise by blood clots or caseous masses.

The characters of the urine are of great importance. Clear or only slightly cloudy at the commencement, it becomes distinctly purulent. Pyuria will sooner or later occur. After voiding, the urine remains cloudy, and if allowed to stand in a test-tube a grayish, chalky layer falls to the bottom. The remaining urine retains its cloudy aspect. The urine is acid and may or may not contain a small amount of albumen. It has been maintained that in renal tuberculosis the urine is always acid, while in other types of pyuria it is alkaline. It has also been said that when the urine in the case of renal tuberculosis contains albumen the latter is due to a parenchymatous nephritis. All that I can say is that a marked amount of albumen would indicate a chronic nephritis or amyloid degeneration of the kidney.

The urea is normal in quantity; an excess in the

*C. G. Cumston, "The Patheogenesis and Treatment of the Symptom Hematuria."—*Am. Journal of Urology*, January, 1907.

phosphates and occasionally the urates is met with.

Microscopically one finds leucocytes, fat globules, blood cells and epithelia coming from the renal pelvis and bladder. In my experience, in about fifty per cent. of cases the specific bacillus will be found in the urine.

To sum up, it may be said that the pyuria of renal tuberculosis presents three characters, namely, its spontaneity, constancy, and durability. Its abundance corresponds to the progress of the lesions. It may be intermittent when complete or partial retention occurs, in which case pain will be complained of and there is an elevation of the temperature. If the obstruction is overcome and the renal pelvis empties itself, there is usually a return to a better condition of health.

When fully developed, the vesical symptoms and pyuria will prevent any mistaken diagnosis of a tuberculous kidney with a tumor of the liver, spleen, or intestine. In many cases the differential diagnosis must be made between renal tuberculosis and tumors of the kidney. Here, the age, the sex, and examination of the urine, especially when the specific bacillus is absent, will be the elements to consider. In malignant disease of the kidney, the tumor is always larger than that of the tuberculous kidney even in the advanced state, and is more frequently met with in young children and in people advanced in years than in adults. Sarcoma is the most ordinary type of malignant growth in children and may or may not be accompanied by severe hematuria. I would also point out that there are instances of renal tuberculosis in one kidney and malignant disease in the other. As far as I am aware, there is no way of differentiating renal syphilis from tuberculosis.

If the specific bacillus cannot be found in the urine the case may be one of pyelonephritis following renal lithiasis, but the *x*-rays and the clinical history will be of great importance. If no shadow of a calculus can be discovered after several essays have been made, it does not mean of necessity that no stone is present, because I have had several cases where it could not be detected on the plates and, nevertheless, at operation the kidney contained beautiful specimens. The character of hematuria in lithiasis, if it occurs, the repeated paroxysms of colic followed or not by the passage of a calculus and a very great sensitiveness when pressure is applied over the kidney, are all excellent diagnostic signs. These symptoms may, however, in some cases be very mild, and, likewise, instances of renal lithiasis and tuberculosis in the same kidney are known.

The symptoms of a non-tuberculous pyelonephritis occurring in a patient presenting tuberculosis in other organs may, of course, cause a diagnostic error. The tuberculous form should not be mistaken for the ordinary types of infectious pyelonephritides, or those arising during acute infections. The history of the case will usually lead to the correct diagnosis, and then again, in the latter case, the pus is homogeneous, while in renal tuberculosis it is granular, thick, and sometimes streaked with blood.

A differentiation of pyuria due to a non-tuberculous cystitis must be made with that of a symptomatic pyuria due to renal tuberculosis. In the latter, the quantity of pus is very large, the lumbar region is sensitive, and there will be abdominal rigidity on palpation. In these cases all treatment directed against the cystitis will be of no avail, the vesical lesions only becoming cured by the removal of the diseased kidney, when the case is one of unilateral renal tuberculosis. When the specific bacillus is absent microscopically from the pus, it by no manner of means indicates that the process is not tuberculous, and in every instance inoculations should be made in animals. The diagnosis of the vesical symptoms and pyuria of renal tuberculosis with similar ones arising in tuberculous cystitis accompanied by hematuria, can only be made by cystoscopy.

The following case, which I reported to the American Urological Association in 1903,* is of interest in many respects. The patient, a young woman twenty-seven years of age, was referred to me in February, 1897, for the removal of a large bunch of tuberculous axillary glands on the left side. She gave the history and presented the signs of a cured tuberculous process in both pulmonary apices. The operation for the removal of the glands required a very extensive dissection, but the patient made an uninterrupted recovery, and was discharged to all appearances cured. About two and a half years later she again returned, this time for symptoms pointing to some disturbance of the urinary apparatus. She had, on several occasions within the last few months, passed considerable blood from the bladder, and at the time she presented herself she was complaining of considerable pain both before and after passing the urine, and a constant desire to empty the bladder. Cystoscopic examination showed a small ulcer near the left ureteric orifice, with a gray fundus and irregular, ragged borders. Palpation of the left kidney showed that the organ was considerably enlarged and painful. The right kidney could not be palpated. From these facts a diagnosis of tuberculosis of the left kidney was made, and removal of the organ was advised and accepted.

At the same time the patient called our attention to the fact that a gland the size of a walnut had made its appearance about a year after the operation in the axilla, and by palpation it could be distinctly felt. Nephrectomy was done and a large kidney presenting the typical macroscopical lesions of advanced chronic tuberculous nephritis was removed. The parenchyma contained numerous caseous foci, and, on section, a few pearly gray tubercles were also discovered. The ureter, a portion of which had been removed along with the kidney, was also studded with miliary tubercles, while its mucous membrane showed a marked purulent infiltration. The patient did well for a few days, but she then developed symptoms of renal insufficiency and died exhausted twelve days later. It should be pointed out that at this time ureteral catheterism and urinary segregation were not commonly done, but had a comparative analysis been made of the two urines it is more than likely that the urine coming from the supposedly healthy kidney would have given evidences of its impaired functions, and I consequently would not have operated. Autopsy showed that both upper lobes of the lungs were adherent, and the prices contained much cicatricial tissue. Strangely enough, the right kidney and ureter were macroscopically normal but, unfortunately, no histological examination was made. The remains of the left ureter were greatly dilated and the mucosa studded with miliary tubercles. Near the left ureteric orifice several small ulcers were found in the vesical mucosa, but their diminutive size caused them to be overlooked at the cystoscopic examination. In this case it would appear that the tuberculous infection did not directly attack the kidney. A metastasis oc-

*C. G. Cumston, Notes on Two Cases of Urogenital Tuberculosis, *New York Medical Journal*, May 30, 1903.

curred in the left axillary glands in the first place and after their removal, which was done as thoroughly as possible, another infected gland developed in the site of the operation. It is my opinion that the renal infection started from this large lymph-node, the process being quiescent in the lungs, but the bacilli prospered in the lymphatics and from here invaded the kidney, probably by way of the circulation.

In cases of unilateral renal tuberculosis, the healthy kidney may give rise to pain of a reflex nature. The bladder is not infrequently sensitive, although it may contain no lesions. This is due probably to an irritation of the neck of the bladder from the irritating properties of the urine. A renal inflammation will, in many instances, cause a frequency of micturition and sometimes this function is extremely painful.

In the commencement of the renal process the general health is not changed, but when it has progressed the symptoms are those met with in any tuberculous infection, such as loss of flesh, night sweats, and elevation of the temperature. If there is a retention in the renal pelvis of the toxic products, there will be anorexia, vomiting and insomnia, chills, and sweating; in other words, all the symptoms of a septic infection.

I am here referring to cases of unilateral renal tuberculosis only, and where a careful general examination of the patient has revealed no cause for his condition.

The diagnosis of renal tuberculosis having been made and after having established whether it is primary or secondary, one must then diagnosticate the condition of the other organs, the ureter on the diseased side, the bladder, and especially the other kidney, because the indication for surgical interference is entirely dependent upon the functional condition of the latter. The ureter on the diseased side is nearly always involved and will be found indurated and thickened, sometimes sensitive. Cystoscopy and segregation of the urine or ureteral catheterism should never be neglected, but personally I have obtained as good results by segregation, and am inclined to prefer it as the technique is much simpler. As the technique of this examination is a special one, I merely refer to it without going into any detail.

Inspection of the lumbar region and palpation will sometimes show that the healthy kidney is increased in size, this being the result of a compensatory hypertrophy and is eminently favorable as far as the indication of nephrectomy is concerned. On the other hand, it may be symptomatic of a tuberculous pyelonephritis which is an absolute contraindication for operative interference, and this can only be settled by comparative analysis of the two urines. If the urine is normal from the healthy kidney and the organ enlarged and painful by palpation, this is probably due to a physiological hyperemia of the organ and does not contraindicate nephrectomy.

In dealing surgically with unilateral renal tuberculosis two operations are indicated, namely, nephrotomy and nephrectomy. Partial resection of the kidney is rarely feasible and personally I have had only one case, for that matter successful, in which I deemed it indicated. As this case has been recently published in the *American Journal of Urology* and as the indications for renal resection have been pretty well discussed in the paper, I shall dismiss the question here.

To justify interference in unilateral renal tuberculosis, we must be sure that the kidney to be operated on is the diseased organ; also the probable degree of its involvement, and that its fellow is functionally healthy. Nephrotomy is indicated in order to drain the kidney and its pelvis in cases where the ureter has become occluded, resulting in a pus-kidney. It has also been advised in cases where the organ has become so completely disorganized that its functional utility has become nil, and when the patient's condition is so bad that primary nephrectomy would in all probability be fatal. The following case will, perhaps, serve as an illustration:

Male, thirty-three years of age, presented no family history of tuberculosis. For the past four months he had had frequent micturition both day and night. He had never to his knowledge passed any blood. The urine voided in my presence was turbid and, when allowed to stand, formed a considerable mucopurulent deposit at the bottom of the tube, the urine above remaining cloudy. Microscopically it was loaded with tubercle bacilli and pus. Palpation in the right renal region revealed a tumor the size of an adult fist, immovable and somewhat sensitive. The left kidney could not be palpated. The diagnosis of right-sided renal tuberculosis was made.

About six months later I was asked to see this patient at his home some distance out of town. For the past three months, so his doctor informed me, the urine had become quite clear with an almost complete absence of pus, but that the patient's general condition was fast failing. He had developed an evening rise in temperature, complained bitterly of indigestion, had lost twenty pounds in weight, and sleep was greatly disturbed. Occasionally he would have a chill. From this history it was only too evident that the patient was suffering from an occlusion of the right ureter which had resulted in a pus-kidney. Palpation showed that the right kidney had increased nearly twice its dimensions since the patient was seen six months previously and distinct fluctuation could be made out. A specimen of urine was obtained and an analysis showed that it was devoid of pus and tubercle bacilli. As the patient's condition was serious, it was impossible for me to await the results of animal inoculation and nephrotomy was done two days later.

A transverse lumbar incision was made on the right side and the kidney quickly reached. The organ was very adherent to its fatty capsule and greatly enlarged. An incision along the convex border was made directly through the parenchyma, that is to say, what was left of it, into the renal pelvis, which gave issue to about a pint of dirty yellow fluid containing an abundance of caseous masses. Two large drainage tubes were inserted and the wound packed with iodoform gauze.

The patient recovered very well from the operation and by degrees recovered a fair condition of health. A fistula exists and gives issue to a large amount of mucopus daily, requiring two changes of dressing in twenty-four hours. He is under the observation of his physician, and if he reaches a satisfactory condition of health I shall attempt secondary nephrectomy. It is now five months since the operation, and although this observation is to be considered as yet incomplete, I have reported it nevertheless, as an illustration of what may occasionally be expected from nephrotomy.

Out of a total of fifty-three operations on the kidney that I have done, eight interferences were for renal tuberculosis, one case being a localized

tuberculoma in the lower pole of the kidney so that resection of the organ could be done; six primary nephrectomies with one death and the case of nephrotomy above reported. Nephrotomy in cases of renal tuberculosis has not often resulted in a cure of the process and almost all of them have fistulæ. These fistulæ inconvenience the patient greatly, but they should not be interfered with if the opposite kidney is functionally insufficient. In instances of fistula giving exit to both pus and urine, a secondary nephrectomy should be undertaken as soon as the patient's general condition is sufficiently good to withstand the interference, in order to do away with the suppurative process, but of course the functional condition of the opposite kindey must be carefully studied in order to be assured of its integrity.

In considering the ultimate results of nephrectomy, the influence of this operation on the patient's general health and life must be considered, likewise the local results of the interference. When the second kidney is healthy, it is little influenced by the removal of its fellow, and if it has undergone compensatory hypertrophy it will carry on its functions perfectly. Two of my cases of primary nephrectomy, done respectively seven and five years ago, are to my knowledge alive and well at the present time. One done three and a half years ago is well other than for chronic rheumatism, while the remaining two I have lost sight of. In primary nephrectomy a persistent fistula is very infrequent and none of my cases presented one. In tuberculous pyelonephritis with marked distention, the closing of the fistula may be a matter of months. However, this usually occurs within a year. There is no doubt that fistula arising after nephrectomy is due to a suppurative process, because nephrectomy done for a renal neoplasm never gives rise to this complication. A pyelonephritis causes two special changes to take place. The first is a sclerous transformation in the fatty capsule which, by keeping the walls of the abscess spread apart, results in a fistula, the formation of which is quite similar to pleural fistulæ. The suppuration and the extension of the infectious lesions of the ureter can be avoided by suturing the end of the canal into the lower angle of the incision after removal of the kidney, and later on destruction of the mucosa may be attempted if the fistula is persistent and gives issue to much pus.

Ureterectomy is a difficult operation, tedious and long, but in certain cases it must be attempted, although personally I have never been obliged to resort to it.

Primary nephrectomy, of course, has no preventive action on a future tuberculous process, and the patients will always remain predisposed to this infection; but I can say that in many instances lesions of the bladder when not too advanced, or of the prostate or seminal vesicles, have regressed and have been recovered from after removal of a diseased kidney.

The technique of nephrotomy and nephrectomy is to be found in all the textbooks, and therefore I shall not refer to it, but there is one point which I would like to consider, subcapsulary nephrectomy. If the fibrous capsule is intimately adherent with the perirenal fat, subcapsulary decortication of the kidney must be done, leaving the fatty capsule, which is thickened and very adherent, behind. The decortication should extend down to the hilum and the ureter should be ligated carefully at this point, after which the kidney is removed. Before closing the wound, which naturally must be carefully drained, the fatty capsule should be curetted as freely as possible in order to remove this diseased structure and thus lessen the tendency to fistula.

Primary nephrectomy should be done in those cases where a positive diagnosis of unilateral renal tuberculosis has been made and the functional integrity of the other kidney has been assured by proper investigation. This is the only rational treatment under these circumstances and will be very largely successful if these cases are diagnosticated early and the operation promptly performed.

In closing, I would again repeat that at present we positively know that there are many cases of primary unilateral renal tuberculosis, and in these removal of the kidney, before other manifestations of the affection have arisen in the urogenital apparatus, will result in a permanent cure. The operation should always be performed through lumbar incision because, although not always the easiest method, it gives a very much lower mortality than the transperitoneal route, which I believe should only be resorted to in nephrectomy for tumors of the kidney.

SOME COMMENTS ON THE ETIOLOGY AND TREATMENT OF INTESTINAL HEMORRHAGE.*

By GEO. M. NILES, M.D.,

ATLANTA, GA.

It is the purpose of this article to discuss only the etiology and treatment of intestinal hemorrhage, or enterorrhagia, in its various manifestations. The symptomatology and diagnosis will be touched only incidentally, and, should some of the statements embodied here seem iconoclastic, it is to be hoped on the other hand there will be advanced enough constructive thought to atone for it.

From a therapeutic standpoint hemorrhage from the intestine may be classed as the inaccessible, except that from the rectum and part of the colon. This loss of blood may arise from many morbid conditions, especially anatomic lesions of the intestines. It may occur in the different kinds of ulçeration, in acute catarrh, in toxic inflammation of the intestine, in irritation brought about by excessive use of laxatives, in injury, neoplasm, hemorrhoids, in embolism of the mesenteric artery, in general venous hyperemia of the intestine due to diseases of heart or lungs, in stasis of portal system, most frequently in cirrhosis of the liver, in volvulus and intussusception, and sometimes after reduction of strangulated hernia.[1] Occasionally small venous varicosities in the small intestine, as mentioned by Nothnagel, may produce it, and, as the patient suffers from no other disorder of the digestive system, may present a very puzzling condition. That this same accident may happen in small arterial aneurysms is claimed by some; also is mentioned aneurysm of the branches of the hepatic artery. Nauyn reports several cases in which cholelithiasis was the immediate cause of the rupture of an artery. Associated with certain hemorrhagic diseases or diatheses, such as purpura and scurvy, and in some infections as septicopyaemia, yellow fever and pernicious malaria, hemorrhage may occur without preceding alteration in the mucous membrane of the bowel.[2] There may be under these conditions an

*Read before the Medical Society of the Fifth Congressional District of Georgia, held at College Park, May 25, 1909.

extravasation in the mucosa from which the hemorrhage arises.

An interesting case of hemorrhage from the intestine caused by carcinomatous polyposis of the colon was recently reported by Babler, Niebruegge and Fisch, of St. Louis.[3] There was a more or less constant discharge of blood from the bowel for about three years. Shortly before death the appendix was removed, but a positive diagnosis was not made until the autopsy. Other clinically important causes are severe icterus, phosphorus poisoning and morbus maculosus. Bayer reports a fatal case following the disappearance of an attack of facial erysipelas. Though some writers disbelieve that enterorrhagia ever manifests itself as a vicarious menstruation, the writer has seen one instance that clearly proved its occurrence.

Leichtenstern has argued ingeniously that intestinal hemorrhage is caused in most cases by a nutritional disturbance in the vessel walls, brought on by failure of one of the most important factors in metabolism—the functions of the liver. His theory, though plausible, is hardly convincing. The tendency to excessive hemorrhage during typhoid fever is correlated by Wright and Knapp with diminished coagulability of the blood, and may occur even apart from the ulceration.[4]

Bamberger has arranged an interesting table showing the frequency with which hemorrhage occurs in different diseases. His deductions seem to prove that it is most frequent in hemorrhoids and in dysentery, typhoid fever and carcinoma of the colon, in the order mentioned. Other etiological factors are clinically important, but much less frequent.

Bériel describes a condition he call "hematemesis from the lower bowel," in a case of hour-glass stomach, in which there was a large gastric ulcer on the distal side of the contraction.[5] In this connection Rolleston reports hemorrhage from the bowel to the extent of a pint without hematemisis in a patient with a rapidly growing and ulcerated carcinoma invading the cardiac orifice of the stomach.

From the foregoing it will be seen that in loss of blood from the bowel, the origin or causation may sometimes be placed easily; or there may be extreme difficulty in determining where the trouble lies. One caution as to hemorrhages of obscure origin should be emphasized; always bear in mind that distended hemorrhoidal veins high up in the rectum may give rise to frequent and alarming hemorrhages in otherwise healthy individuals.

Regarding the treatment some general principles may be laid down applying to severe hemorrhage above the rectum. Physical and psychic quiet must be maintained, and anything tending to increase peristalsis, raise the blood pressure, or cause decomposition of intestinal contents must be sedulously avoided as far as possible.

Right here the writer wishes to condemn the use of cold applications, and to indorse the views of Leube, who says "The application of cold to the abdomen, either in the form of an ice-bag, ice-compresses, or Leiter coil, is essentially valueless, for the cold cannot possibly exert any direct influence on the bleeding spot." The possible reflex benefit to be obtained from cold is more than counterbalanced by the probable excitation of peristalsis; besides, few patients find these applications comfortable.

Should there be enough strength to admit it, no food should be given by the mouth or rectum for forty-eight hours, and no fluid except cracked ice sparingly. After this time only liquid foods should be allowed for a week longer, in the discretion of the physician.

Opium, another sheet anchor in the treatment of inaccessible intestinal hemorrhage, should be used sparingly, if at all, and then only in the form of morphine hypodermatically to calm bodily restlessness. To give enough opium to lock the bowels, thereby permitting their contents to undergo putrefactive decomposition, will defeat the main object in view.

Ergot, also, is an idol that should be taken from its pedestal. In addition to the writer's experience with this drug, which has been wholly unsatisfactory, permit the following quotations: Cushney—"In other forms of hemorrhages—from the stomach, intestines, kidneys, lungs, or uterus (excluding post partum hemorrhage)—in which the bleeding point cannot be reached, it is often advocated in the belief that it contracts the walls of the vessels and thus arrests the flow of blood. These hemorrhages so often cease spontaneously that it is difficult to estimate the value of any remedy, but it may be questioned whether ergot merits its reputation in these cases."[6] Rolleston—"Although hemorrhage may stop after ergot has been given, it is doubtful whether ergot has a beneficial influence on hemorrhage, except from the uterus."[7] Stengel—"Ergot, hydrastis, and turpentine have been used in the treatment of intestinal hemorrhages, but are of doubtful value."[8]

The collapse of anemia, as from any other hemorrhage, must be treated by external heat, counter-irritants or transfusion with saline solution.

The control of bleeding from the rectum will be briefly covered. As in this condition it is possible to reach the lesion, enemeta of ice water may be used. To these, if desired, may be added styptics as tannin, alum, acetate of lead, nitrate of silver, or adrenalin. The writer has used with much satisfaction a suppository suggested by Dr. Boardman Reed containing three grains each of suprarenal extract and iodoform, and 2 minims of ichthyol, given half an hour before the bowels are to be moved, and one after movement.[9] Further treatment is surgical and need not be described here.

Hemorrhages high up in the rectum or descending colon may be reached by ice cold or astringent injections, but these should not be used until other methods fail, as they tend to keep up undue peristalsis. Tampons of iodoform gauze, as recommended by a recent writer, are only mentioned as being likely to do much indirect harm and little direct good.

When the hemorrhage occurs from the transverse colon on up to the duodenum, remedies to control it must be given by the mouth or hypodermatically. Where there are slight and more or less frequently occurring hemorrhages, the bismuth salts—preferably the subgallate—in doses of 15 grains three to six times daily, are generally effective. Slightly more energetic in their action are tannic acid, tannigen, tannalbin, or tannigenaform in doses of 5 to 10 grains four to six times daily, but they often upset the stomach when continued more than three or four days.

When the bleeding assumes an acute form, and active measures are necessary, the remedies most efficacious are adrenalin, gelatin, and calcium chloride in the order stated.

Since 1901 adrenalin extract has been recognized as having important hemostatic properties, and while

its action on accessible hemorrhages has been fairly well understood, its effect on inaccessible intestinal hemorrhages has been in some doubt. Several have endeavored to clear up this subject, the most recent investigator being Dr. Carl J. Wiggers.[10] From a number of painstaking and enlightening experiments he draws the following conclusions, which are indorsed by the writer: (1) Large doses of adrenalin (from 0.05 to 0.1 mg.) cause a short preliminary increase in hemorrhage, followed quickly by a decrease or cessation of bleeding. On account of the great preliminary loss of blood they are always contraindicated. (2) Small doses of adrenalin (from 0.1 to 0.25 mg.) cause little or no preliminary increase, but shorten the course of the hemorrhage. As they save the red blood cells in every way, they are therapeutically desirable. (3) The method of introducing adrenalin determines the effect on blood pressure and hemorrhage. No results are obtained by subcutaneous administration. By continuous intravenous injection of weak solutions a slight elevation of pressure can be maintained and hemorrhage be simultaneously checked. This can also be accomplished by intramuscular injections. (4) Adrenalin is not indicated in all intesinal hemorrhages. The condition of the blood pressure is the criterion for its use. In hemorrhages of short duration, where the pressure has not fallen to any extent, a judicious use of nitrites proves of more benefit than adrenalin. When the bleeding has been profuse, however, and a low pressure already exists it becomes vital that hemorrhage should be checked without further reduction of pressure. Adrenalin finds its use in this field."

In 1896 Dastro and Floresco demonstrated that blood drawn from a dog into which a 5 per cent. solution of gelatin had been injected intravenously solidified almost immediately, and that the same results could be obtained by adding gelatin to the blood outside the body. In 1898 Lancereaux and Paulesco found that subcutaneous injections of gelatin were quite as efficient. Taken internally the unaltered substance has a marked local hemostatic effect, but it is doubtful if this can be obtained from the products of gelatin digestion. For this reason it is best that entire peristalsis be not checked when this agent is given by the mouth. When thought advisable gelatin may be given hypodermatically (3 to 5 fluid drams), and also by the mouth (1 to 8 fluid drams) in a 10 per cent. normal salt solution. It is fair to state, though, that Da Costa deprecates the use of gelatin hypodermatically, rather, in the opinion of the writer, overestimating the danger of thrombosis.

The chloride and lactate of calcium have seemed to give good results by increasing the coagulability of the blood, though there is some skepticism in high quarters regarding the absorbability of the calcium salts by the intestinal surface. Dr. Robert Coleman Kemp strongly recommends either the chloride or the lactate of calcium (grs. 10) well diluted every two hours. The chloride of calcium and gelatin may be given together, if desired, an eligible form being Tremolier's solution, which is a five per cent. solution of gelatin and a two per cent. solution of the calcium chloride. The writer has frequently alternated Tremolier's solution and gelatin with satisfactory results. Another hemostatic agent of merit is the lactate of strontium, which may be given by hypodermoclysis in doses of 15 to 30 grains.

Atropine, as a hemostatic, is being investigated at present, but its beneficial effects so far do not rest on a physiological basis.

It is well, especially in bleeding from duodenal ulcer, to endeavor to keep the bowel contents alkaline by the administration of some efficient antacid such as sodium bicarbonate in full doses.

After the active hemorrhage is arrested it is advisable to continue these agents, either in smaller doses or at longer intervals for several days, during which time rest and strict dietetic precautions should be enjoined.

Should all the measures mentioned fail, surgical aid will of course be demanded, for in the case of malignant neoplasms, erosion of large vessels by ulceration or otherwise, or some forms of hemorrhoids, medical treatment or local applications will necessarily be futile.

If, however, the suggestions indicated in the foregoing are intelligently and methodically followed, the cases of intestinal hemorrhage requiring surgical intervention will be reduced to a minimum.

AN AMERICAN SCHOOL OF TROPICAL MEDICINE.*

By ISAAC WILLIAMS BREWER, M.D.,

Fort Warren, Mass.

Whether we approve or not, the United States has expanded, and become a colonial nation, assuming all the complexities of tropical administration. Not the least of these new problems that have come to the nation, are those relating to the sanitary administration of our new possessions, and upon their solution depends in a large measure the outcome of our tropical ventures. These problems must be met and solved by American physicians working in the tropics in conjunction with native physicians. The men who are to do this work must be carefully instructed in the many duties they will have to perform. Sir Patrick Manson spoke very feelingly upon this subject in his Lane lectures,[1] saying: "To send a young fellow fresh from the schools to some tropical and unhealthy climate to treat diseases he has never seen before, many of which he has never heard of before, is not only cruelty to the doctor, but it may be death to the patient and bad business all around. A merchant would not think of running his business on such lines. Why, then, should the medical business, the most important of all business, in that it deals with human life, be run on such lines? I could cite hundreds of instances in illustration of the folly, I might also say the criminality, of the old system, by which raw, untaught and inexperienced youths were launched in the tropical service. Many of these illustrations, I am sorry to have to say, would be culled from the long category of my personal mistakes."

*Read by title at the sixth annual meeting of the American Society of Tropical Medicine, held at the U. S. Naval Medical School, April 10, 1909.

Doctor F. C. Wellman[2] who has spent many years in tropical Africa says: "The successful settlement of the tropics is of the greatest importance to the world. Such settlement depends in no small measure on the solution of various hygienic and epidemiological problems there obtaining. In the absence of this knowledge an extra expenditure of lives and money is certain to ensue. The problems in question can best be studied by trained observers working at first hand, in other words, by scientific men living in the tropics. With these points before us there is no occasion for me to dwell on the necessity for adequately equipped pathologists, clinicians and sanitarians, especially trained in the lines along which their investigations will run, to take up the enormous task awaiting them. It is no less than a cardinal sin to send poorly equipped men to the tropics."

Doctor George Dock[3] of New Orleans says: "Another pressing need is more extensive activity in the investigation of tropical diseases in the United States. I would not for a moment minimize the splendid advances made by private individuals, as well as by various departments of the government, but the field is unlimited and includes the diseases of all lower animals as well as man. The valuable results of the schools of Tropical Medicine of Liverpool, London and Hamburg show what may be done and what should be done by all countries having similar problems."

The physician who goes to the tropics to practice finds his duties very different from what they would have been had he remained at home, and the maxims taught by preceptors do not seem to apply to the conditions under which he is living. He is confronted by a host of strange diseases. The irruptive fevers which occupy so much attention at home are less prevalent, while malaria, and diseases of the alimentary canal are very common. Skin diseases, of which many practitioners in this country know very little, are prevalent and perplexing. The microscope is to be his daily companion and there are but few accommodating laboratories where such work can be done for the asking. The examination of the stools must be a routine. The study of the mosquitoes, both in the adult and the larval stages, will occupy much time, and the superintendence of the abolition of their breeding places will require tact and good judgment. This is really the work of the engineer, but there will be no engineer and the doctor will have to fill his place. There are a host of undetermined fevers in the tropics which must be studied with care before any progress towards their prevention can be made. The inspection of food, a subject which is practically untaught in our schools, must be a daily duty. In fact, in addition to the ordinary work of a physician or surgeon, the practitioner in the tropics will have to fill all the positions on the board of health from sanitary engineer to food and meat inspector. Besides he must be a medical zoologist, a bacteriologist and a diplomat.

Have the graduates of our medical schools been sufficiently instructed in all of these specialties? We may safely answer no!

Recent inquiry of the leading medical schools in this country has shown that although they all recognize the importance of instruction in tropical medicine there is no place in the United States where such instruction can be had. Doctor John M. Swan has established a laboratory course in tropical medicine at the Philadelphia Polyclinic, but he informs me that the instruction given does not include clinical teaching, and it is doubted very much whether satisfactory results can be obtained without bedside teaching.

Medical zoology occupies a small place in the course at medical schools in this country. In the Philippines this is probably the most important branch of medicine. I have more than once seen good practitioners who on their arrival there were entirely unacquainted with the amoeba or the intestinal parasites.

Hygiene, although occupying much of the attention of the public, is practically untaught in most of our medical schools. Yet in the tropics every physician has to be well posted in this branch of medicine.

The days when a physician isolated from contact with his fellows could by hard work and careful observation become a good and useful practitioner of medicine are passing away. The progress of medical science is so rapid that a few years of isolation puts a man behind. Especially is this true in the realm of tropical medicine where there are so many new discoveries in etiology and treatment.

If we are to obtain the best results from the men who are to represent our country in the tropics we must provide some means whereby they may become reasonably proficient in their many duties before they leave this country. Most of the colonial countries of Europe have recognized this and have provided schools where such instruction can be obtained. The London School, the oldest of these, has been in existence for about ten years and has had something like seven hundred students. Many of the graduates are now filling posts of importance in the tropics, while not a few have added materially to the world's stock of knowledge. This last is especially true of the Liverpool School, which has sufficient funds to provide for commissions to study the diseases of the tropics in the endemic areas.

Our laboratory workers and sanitarians in the tropics have accomplished much of which the nation is justly proud, but there is so much to be done that we should do all we can to obtain facilities for training men to continue the work which has begun so brilliantly.

The work so far has been mostly done under the auspices of the government, but it is well known that our legislators are averse to making appropriations unless they bring immediate returns, therefore there will come a time when this work will be abandoned by the government, and we should therefore provide an institution to continue this important work, an institute for the study of diseases peculiar to the warmer regions of the globe. There should be attached to this institution a well-appointed hospital and a school for the instruction of physicians in tropical medicine and hygiene. It should have sufficient funds to send experts to study the diseases in their endemic areas. The institute should be closely affiliated with the laboratories in Manila, Porto Rico, the Canal Zone, and Hawaii, and should make arrangements for an exchange of workers so as to advance the work as much as possible. Practitioners in the tropics should be encouraged to send there pathological and other interesting specimens, which should be kept and made available for study by those interested in the subject. This institute should be the "home office" of the tropical practitioner and a gathering place for all interested in the advancement of medicine in the tropics.

The services of the trained specialists of the in-

stitute should be at the disposal of the government whenever needed. They should also aid the workers in the tropics with their experience and advice as much as possible.

The study of the so-called tropical diseases is not only of importance to those who dwell near the equator, but also to the entire world. Many of these diseases are only relatively tropical. Within the past few years several of these diseases have been found to prevail extensively in the warmer portions of the United States.

Our ignorance concerning conditions in the tropics is appalling. We know nothing of the proper diet for the white race in such regions. There are those who believe one should live as the natives do and abstain from meats, while others say the beef ration should be liberal. One student of tropical medicine tells us that the cause of the decay of the white race in the tropics is the intense light. He also advocates the liberal use of alcoholic stimulants. Others of long tropical residence deny these premises. These points and many others should be determined scientifically, for if we are causing disease amongst our countrymen who are working in the tropics by overfeeding them or by exposing them to the intense light the sooner we know it the better.

There are no doubt many men who could furnish the funds for such an institute if they were aware of the importance of the work to be done. It has been estimated that $500,000 will provide for the school, and as much more would make a good foundation for the other work. Once the foundation is laid smaller sums will be forthcoming to provide for special work.

During the last few years there have appeared a number of papers advocating the establishment of an American School of Tropical Medicine. Most of these have boomed some city as the most desirable location for the school. This has done good by keeping the question alive, but it does not seem wise at this time to expend our energy discussing the merits or demerits of any city, but rather to make a united effort to secure the funds for the foundation of the Institute, leaving the question of location to a committee of physicians as was done in locating the Rockefeller Institute. The important points to consider in choosing a location are the supply of clinical and laboratory material and the convenience of the students.

A CASE OF PARENCHYMATOUS KERATITIS IN ACQUIRED SYPHILIS.*

By BURTON CHANCE, M.D.,

PHILADELPHIA.

ASSISTANT SURGEON, WILLS HOSPITAL.

Occasionally we see cases of parenchymatous haze of the cornea in individuals of thirty or upwards, who claim that they have always been robust; whose family history is vigorous; whose persons are not blemished by the facies of inherited syphilis, when, in spite of this, one feels justified in assuming from the appearance of the cornea that luetic infection is at the bottom of the disease, and especially so when the disease ends promptly after brisk mercurialization. Interstitial, or parenchymatous, keratitis due to acquired syphilis was regarded, in my early days at Wills Hospital, as problematical, and American writers on the subject were indeed very few in number prior to 1900. Since then, however, numerous instances of the disease have been recorded with indubitable evidence. Last year two important reviews were published (by A. E. Davis, at the Chicago meeting of the American Medical Association, and John T. Carpenter, at the meeting of the American Ophthalmological Society) which, to my mind, have fixed the subject definitely as an ophthalmologic entity; and by the recital of five additional cases these authors have amply justified the contention. Each author begs that forgotten cases may be recalled and that American surgeons report any they may have had so that doubt on the subject may no longer exist. Hospital records are so incomplete and often so abruptly cut short that one gets from the study of them only the most unsatisfactory results. In all the years I have been connected with the hospital I have seen there only one case and none in my private practice.

The present case, which Dr. Schwenk very generously allows me to report, is undoubtedly one of specific infection. Our opinion at the time the patient attended the hospital, however, was formed solely because of the accompanying symptoms.

The patient presented herself at the hospital in February, 1900. She was tall and of large frame, and apparently was a healthy woman. She came from one of the quiet towns in the interior of Pennsylvania. She was twenty-four years of age and had been married a year or so. She had one child, a well-developed nursling. The woman stated that at about the time the baby was born, in November, 1899, her left eye became reddened, tears flowed rather freely and her sight was foggy. There was but little pain, and after a while, in the midst of her new cares, the symptoms gradually disappeared or became less noticeable. In January, 1900, however, three weeks before coming to the hospital, the symptoms returned with increased severity. After a few days there came a lull, but three days before we saw her they returned, and this time with great pain.

Upon examination there was found intense tarsal and bulbar injection with deep ciliary congestion and tenderness. The cornea was steamy, the anterior chamber deep, and the iris discolored, the pupil 3 mm. and fixed. Atropine solution was repeatedly instilled, which after some time effected irregular dilatation, disclosing several posterior synechias. The vision of the right eye was 5/10; of the left 5/35. Ophthalmoscopically the right disk showed a very deep cup, yet the fundus was apparently healthy. The left cornea was too hazy for a satisfactory examination. The pupil was occupied in the lower part by a tough exudation. Atropine was prescribed for frequent use and mercuric bichloride and potassium iodide in full doses. After two days the lids became edematous; the ciliary injection most intense. The cornea was now seen to be pervaded by a dense haze which was caused by a fine granular infiltration of the parenchymatous lamina. The superficial lamina was not so edematous as at the earlier examination, yet a clear view of the iris and deeper structures could not be obtained. The pupil had become larger, the nasal border of the iris was narrower than that of the

*Read at the April 15, 1909, meeting of the Section on Ophthalmology, College of Physicians, Philadelphia.

temporal, for there it was tightly adherent to the lens capsule, which was studded with small masses of uveal pigment. I leached the temple and ordered iced compresses to be applied incessantly. In two days there was a marked reduction of the edema and superficial congestion, and in ten days the most observable sign was the diffuse opacifaction of the cornea. Through the periphery of the cornea a satisfactory view of the fundus was obtained. There were no gross changes noted, though the vessels were remarkably tortuous.

The patient at this time complained more or less of sore throat and of some discomfort in the nasal chambers. She was thereupon sent to the Rush Hospital for Consumptives and Allied Diseases, where she was examined and treated by Dr. Henry J. Off, who, on March 1, 1900, wrote to me that he had found a large perforation in the nasal septum and specific erosions in the larynx. Mercurials and the iodide were given in increasing doses. On March 8 there was noticed in the lower outer quadrant of the cornea, near the limbus, a small, macerating ulcer. This was thoroughly cauterized with carbolic acid and after three days the epithelium became restored. The iodide solution was again increased, the exact dosage, however, was not recorded, but on March 20, six weeks after the patient was first seen by us, the cornea had cleared so markedly that a testing of the vision showed so great a gain that with weak spherocyclindrical combinations the result yielded 5/5 in each eye. The patient had been greatly reduced during the course of the disease, but now regained so much that she believed herself well and abruptly left the city. We have not heard from her since.

This was evidently the first serious disease of the eye the patient had had. There were no signs of any dyscrasia nor of previous inflammation, and the disease had come on insidiously, without marked symptoms and was confined to one eye. At first the cornea contained a number of grayish punctate opacities, scattered through the parenchyma, which later became more numerous in the center and shortly were formed in a solid sheet so that the cornea became quite opaque. There was but scant vascularity of the cornea and but little lacrymation and pain. In nine weeks from the commencement of the attack the cornea regained sufficient transparency to afford a satisfactory examination of the fundus, where except for dense iritic adhesions to the lens, the exterior of the eye was apparently healthy, and the patient discontinued visiting the Hospital.

As in Collins' case, the cornea in this patient became ulcerated; and, in keeping with the details in certain of the reported cases, there were ulcerations in the nasal and laryngeal cavities. There was distinct iritis at the start, but at no time were there evidences of involvement of the choroid of either eye. It was impossible to obtain a satisfactory or even trustworthy history of syphilitic infection. The patient was high class and most intelligent, and declared she had been in perfect health up to the birth of her child. It may be assumed, therefore, that the infection had taken place within two years prior to the outbreak in the cornea. So prompt was the recovery of the patient after the administration of mercury and the iodide, that we allowed our faith in the empiric "therapeutic test" to rule us, in assuming it to be a genuine case of syphilitic infection.

THE GENERAL PRACTITIONER AS A DERMATOLOGIST.*

By BENJ. F. OCHS, M.D.,

ADJUNCT ATTENDING DERMATOLOGIST, LEBANON HOSPITAL; DERMATOLOGIST, LEBANON HOSPITAL, O.P.D.; ASSISTANT DERMATOLOGIST, HARLEM HOSPITAL, O.P.D.

Perfection in medicine has as yet not been attained. The era of positive diagnosis and treatment seems most likely to be reached through the specialist, for specialism tends not only to the exact knowledge of the class of diseases treated, but also to the treatment indicated. The specialist confines his whole time and thoughts to the particular branch involved, and does not touch upon the other branches, except in so far as they are part of, or in touch with, his specialty. Thus the dermatologist should be conversant with other branches of medicine, for he should not only know how to recognize diseases from their cutaneous manifestations, but should also know their etiology, and if depending on, or in conjunction with other diseases. He must know how to recognize diseases of internal origin from their cutaneous lesions. Many a case of diabetes has been diagnosed first by the dermatologist from the skin lesions presented to him for treatment. And what holds good for diabetes can also be said of many more diseases of internal origin. Thus we have the acne of the anemics, the zoster of the neurotics, the purpura of the rheumatics, the exanthemata, and the skin lesions of the eruptive fevers. Diseases of faulty metabolism, especially in children, are recognized from their cutaneous symptoms. It is from the correct interpretation of these cutaneous manifestations that the dermatologist makes his positive diagnosis; not that his judgment is infallible, but that he is more often correct than is the general practitioner. Mistakes in diagnosis are often ludicrous and quite often of severe consequences. Many of the mistakes in diagnosing skin troubles have had bad, if not fatal, terminations. To mistake a mild case of skin disease for syphilis or for variola will certainly not ease the patient's mind, but, on the contrary, is apt to do much harm, and cases of suicide have resulted from such grave errors of diagnosis. To show a few of the errors of the general practitioners who have referred cases to the writer, he may be permitted to quote that of a physician, who told a young man about to be married, and who consulted him about some skin trouble, that he had contracted syphilis. The young man, very much distracted, promptly called off his engagement, and with his physician called upon the writer, who diagnosed a pityriasis rosea, and in a short time, under appropriate treatment, the patient was cured, was married, and is now in good health. Another of the mistaken ideas of the general practitioner is that the so-called "liver spots" are solely of internal origin, depending on disorders of the liver or gall-bladder. A prominent lawyer was referred to the writer by his physican, asking for some advice in removing these "liver-spots," as all forms of cathartics, chologogues, etc., have failed to remove them. A simple solution of sodii hyposulphite (1-3) cured his "liver-spots." That these may be mistaken for syphilis, the following case will show. Mr. A. was under treatment by his physician for more than six months on account of a supposed syphilis, during which time he had hypodermics of mercury, inunctions, and pil. protoiodide *ad nauseam*.

*Read before the Medical Society of the Borough of the Bronx, April 14, 1909.

and as there was no improvement, the writer was consulted, the diagnosis of chromophytosis was made, and the patient was promptly cured. Thus he was spared a long continued course of treatment, his mind was eased, and he was restored to perfect health. Of course in this class of cases the microscope is of valuable assistance, as we can demonstrate the presence of the *Microsporon furfur* in the scrapings from the affected areas. Scabies also has often been mistaken for syphilis. About a year ago, a patient who had a lesion on his penis and some scratched papules on his body was referred with the diagnosis of syphilis. Careful examination showed the case to be one of scabies, and treatment for this affection proved the corrected diagnosis. Of course the *Acarus scabii* is not demonstrable in every case of scabies.

The general practitioner lays entirely too much stress upon the patient's statement in regard to what he has, and what he has not had, which the physician believes to be the absolute truth. In other words, the patient will sometimes unknowingly deny an infection. We all know that specific infections can take place extragenitally, thus, by the lips, the mouth, and even through the tonsil. (Physicians never contract syphilis in any other way than by the finger.) Ofttimes intra-urethral chancres have been mistaken for gonorrhea. Therefore, while the patient's statement seems correct, yet it is erroneous and leads the physician to make an incorrect diagnosis. To illustrate this the following case will suffice. A patient was referred on account of a long continued skin eruption; he had denied to his physician an infection. Nevertheless the true diagnosis was made from a serpiginous rash, which promptly yielded to proper treatment. Here we see that though the patient was unaware of his infection, and probably would have admitted it had he but known it, he really had acquired such an infection. Though to the dermatologist, who takes no history before examination, the case was clear, yet it was exceedingly confusing to the general practitioner. I repeat that histories are vague, indefinite and untrustworthy. The diagnosis should be made from the cutaneous lesions, and not from the history as given by the patient. I could go on enumerating many more cases, but do not think this advisable.

How frequently pustular syphilis is mistaken for variola, and patients are sent to the pest house, is surely known to you all. Then again cases of variola have been allowed to go around, believing them to be cases of pustular syphilis, thereby allowing numbers of people to be exposed to this most virulent disease. It seems that the general practitioner loses sight of the fact that the skin is the largest organ of the body, and, as the other organs, subject to all forms of ills. The average practitioner recognizes but few diseases which may affect the skin—eczema, acne, and psoriasis. His therapy is limited, and consists chiefly of arsenic internally, and zinc ointment, to which he adds occasionally sulphur or resorcine, externally. And if these therapeutic agents fail him, he thinks the case must be one of syphilis, and the patient is given mercury, principally by mouth, up to the point of salivation, and if all fail to cure the patient, a specialist is called upon. Of course the specialist is asked to make the diagnosis offhand, even though the original disease is masked by treatment. Yet we should not be too severe on the general practitioner, for he has not much opportunity to study dermatological cases, as they are really only a small part of the many cases he is called upon to treat; but were he to pay as much attention to dermatology as he does to the other branches of medicine, he would undoubtedly be farther advanced in this special branch.

Nor is the average practitioner to be blamed for his shortcomings, for as a student, and later on as an interne in a general hospital, where few, if any, dermatological cases are admitted, he acquires but little training in this subject. Therefore these errors in diagnosis seem pardonable. I would strongly advise the various hospitals in this city to have a ward for dermatology, the same as they do for surgery, gynecology, medicine, etc. Then this state of affairs would soon be corrected. In conclusion I would advise the general practitioner to give up some of his spare time to going to the various clinics that are open to him, and studying dermatology from the living subject. This branch of medicine can only be mastered by the use of both the eyes and the touch, and cannot be acquired by studying books and pictures.

1980 Seventh Avenue.

Early Diagnosis of Measles.—E. Apert describes two signs that he considers pathognomonic of measles, and that appear so early in the disease, or so late in the incubation period, that isolation begun at this time will prevent its spread to others in the family. It is not early enough to make the diagnosis when the catarrhal symptoms have appeared. The disease is then infectious and all precautions fail to prevent its spread. The signs that are of value are Koplik's spots and conjunctivitis of the pterygeal area, that is of the conjunctiva between the lids. This appears when Koplik's spots are seen, that is three or four days before the skin eruption, and both signs have disappears when Koplik's spots are seen—that is, three or four on the inner surface of the cheeks, rarely on the inner side of the lips, never on the gums or palate. At first they are like tiny, grayish granulations on the rosy mucous membrane, later becoming bluish.—*Le Bulletin Medical.*

Relapsing Scarlatiniform Desquamative Erythema.—G. Petges describes a form of erythema that is easily mistaken for scarlatina. Its distinguishing points are the absence of marked fever, and severe symptoms, the marked pruritus that precedes it, the very large plaques in which desquamation occurs with an erythematous condition continuing, and the recurrence of the attacks, one patient described by the author having had twenty attacks. It begins with pruritus, malaise, feeling of fatigue, chilly feelings, headache, and inability to sleep on account of the itching. It appears over the entire body. Desquamation begins in a few days and lasts for some weeks. There is no history of contagion. The plaques of desquamated skin are large and very tenacious. The cause of the disease is unknown, but the symptoms are in favor of an infection. It is probably this disease that is mistaken for second attacks of scarlatina.—*Gazette Hebdomadaire des Sciences Médicales, de Bordeaux.*

Osteomyelitis in the New-Born.—H. L. Devraigne says that osteomyelitis when it occurs in young infants begins acutely with high temperature, extreme pain on motion of the affected limb, moaning, and refusal of food. An enlargement of one or other bone is found accidentally. The source of infection may be intrauterine. After birth there are several modes of entry for microorganisms, the principal of which are the staphylococcus, streptococcus, and pneumobacillus. The last form of infection is short, but exceedingly severe. A bronchopneumonia from infective emboli may be a complication. The prognosis is affected by the age of the infant and the number of foci that are affected. When recovery does occur it is quicker and more perfect than in the adolescent. The joints generally recover perfectly, and there are no sequestra, since there is little tendency to necrosis of the bones. Treatment should consist of supportive measures and early drainage of the affected foci. The author recounts a case observed by him in an infant of eleven days, in whom there were eight distinct foci of infection in the long bones. The infant recovered with little deformity.—*Bulletin de la Société d'Obstétrique de Paris.*

CHRISTIAN SCIENCE IN THE ARENA.

IT is curious to see with how little exercise of their reasoning faculties many otherwise intelligent persons are content to go through life. They both accept and offer statements, based upon the flimsiest sort of evidence which would not be accepted even in a police magistrate's court. Facts to them are facts; they never can be made to see that facts can lie like figures or that a few isolated and unanalyzed facts furnish an extremely insecure foundation upon which to construct a weighty theory. These, and other reflections of which charity and lack of space will not permit the expression, are suggested by an article in *The Arena* for March-June, 1909, entitled "Medical Explanations of Christian Science Cures Considered in the Light of Typical Cases." The paper is from the pen of the editor of the magazine who, the Christian Scientists jubilantly proclaim, is not a member of their sect. That they should regard this as adding any weight to his evidence is only another instance of the paresis of the reasoning faculties with which these peculiar people are so sorely afflicted. We suspect, however, that their diagnosis is incorrect in this case; if the author of the article is not a "Scientist" he certainly employs the jargon of the cult in the most approved Eddyistic style. The first case he cites is quoted, he says, "because of the supposed incurable character of the disease and the fact that from the viewpoint of *materia medica* the question of diagnosis leaves nothing to be desired." What the "viewpoint of materia medica" is or what possible bearing it can have upon diagnosis we must leave to Christian Science to explain. "From the viewpoint of the tariff on beans the question of the inflation of the currency leaves nothing to be desired" would be as illuminating a phrase.

The argument of Mr. Flower is that the Christian Science annals contain records of many cures of organic disease, diagnosed as such by experienced physicians, and pronounced by them incurable. He reports at length several cases of the kind, some very doubtful, some of simple eyestrain, but others of true organic disease, the most authentic being a case of blastomycosis which had been diagnosed and treated without success by a number of Chicago specialists. Admitting, however, for the sake of argument, that they were all cases of organic disease, that is to say, disease with demonstrable lesions, as grave and as imminently fatal as the sufferers and their friends and physicians said they were, they prove absolutely nothing. One swallow does not make a summer and one recovery from disease offers but faint presumption of the efficacy of any treatment. The annals of Lourdes and of scores of other shrines and places of pious pilgrimage in Europe and America contain records of a far greater number of "authentic cures" of organic disease than Christian Science can boast of. Father John of Cronstadt had more cures to his credit than has Mother Mary of Boston. The office records of any successful quack contain many instances, genuine ones, of the restoration to health of the apparently hopeless victims of organic disease. But what do they all, multiplied even many times, count in comparison with the thousands upon thousands of deluded creatures who entrust themselves to Christian Science, faith cures, out and out quackery, and the like, and, after a little temporary improvement, such as almost always occurs in chronic cases with a change of doctors—an improvement which is at once chronicled as a "cure" in the misleading records of the cult—drop the wretched imposition and die.

It is in the experience of every medical practitioner to see patients, who have been condemned to death, recover health and strength most inexplicably and contrary to all the rules of pathology. They are in the last stages of incurable disease and they ought, by all the rules of the game, to die—but they live. Tuberculosis is notoriously a spontaneously curable disease; cancer cures itself not infrequently, often belying the unfavorable prognosis of scores of surgeons; the subjects of Bright's disease sometimes fail to die when they are told they must, and so on throughout the list of incurable maladies. These are medical puzzles and the explanation of them is as yet beyond medical science. There is doubtless a reason in each case, and when the modus operandi of the cure is discovered, the science of therapeutics will come into its own. That the psychic element is in some way a factor is perhaps true, but for the present we must content ourselves with calling them spontaneous cures.

That the comparatively few cures in Christian Science of so-called organic disease are instances of spontaneous cure is certain. The only case of all these collected by Mr. Flower in which the possibility of spontaneous cure might be doubted by the experienced physician or instructed layman is the first one recorded, evidently regarded by him as the *pièce de resistance*, the one of blastomycosis. This disease has only recently been recognized as a clinical entity, and physicians in general know but little about it; they read of the severest cases and get the impression from their reading that the disease is incurable. That this impression is incorrect is shown by the textbooks on dermatology which teach not only that the disease is curable, but that spontaneous healing sometimes occurs. Schamberg says: "The prognosis is favorable unless septicemia has taken place." Hyde and Montgomery say: "Healing sometimes occurs spontaneously." Gilchrist, the discoverer of blastomycosis says: "In some cases there was to be noted a distinct tendency to spontaneous recovery." Pusey says: "Spontaneaus in-

volution may occur . . . the prognosis in cutaneous blastomycosis is good." Disproof of Christian Science pretensions is so simple a matter that, did they not mislead so many people, one would really be ashamed to notice them. It is almost as wasteful of good black ink as a denial of the late Brother Jasper's assertion that "the sun do move."

THE EFFECT OF DIPHTHERIA TOXIN AND ANTITOXIN ON THE HEART.

In spite of the decrease in the mortality from diphtheria since Behring's discovery of the curative serum, there still remains a residuum of cases which even after the use of the antitoxin fail to recover. Whether this is due to the too small or too tardy use of the antitoxin, or to an overweaning confidence in serum therapy leading to a neglect of other therapeutic aids, the immediate cause of death is, in a large proportion of such cases, cardiac failure. We are still much in the dark as to the physiology and pathology of this, there being yet a difference of opinion even as to whether the immediate cause of death is a true myocarditis or an injury to the nervous mechanism of the organ; and we are also uncertain as to the therapeutic value of antitoxin once the cardiac symptoms have made their appearance. Some experiments recently carried on by Fritz Meyer and reported in the *Berliner klinische Wochenschrift* for June 28, 1909, are of interest as throwing light on various aspects of the question. This investigator worked with a large number of rabbits and studied carefully the effect of diphtheria toxin and antitoxin given in various doses, at different times, and by subcutaneous and intravenous injection.

As death from diphtheritic intoxication is dependent on, or at least associated with, a marked progressive fall of blood-pressure, Meyer's first investigations were into the effect of the antiserum upon this factor. By giving fatal doses of toxin at various periods following antitoxin injections, he was able to demonstrate three points: Antitoxin, if administered early in sufficient doses, absolutely prevents the fall of blood-pressure; if given later, but before the fall has occurred, it delays its onset; but if given after the pressure has once fallen, it is quite without effect. Noting at autopsy the marked destruction of the suprarenal gland due to the toxin, he administered suprarenal extract subcutaneously, 1 c.c. of the extract in 19 c.c. of salt solution, to animals in which the fall of blood-pressure had occurred, and found that this acted quickly and definitely in raising it again. It was, too, the only agent he could discover which had this action. By another series of experiments the pathological changes in the heart muscle were studied. These were found to consist in a true myocarditis, which made its appearance from six to eight days after the intoxication. Very large doses of the toxin killed the animals before these changes occurred, and very small doses produced no effect. The myocarditis was produced by medium quantities of toxin or by severe intoxication with insufficient doses of antitoxin. The myocardial changes were found in cases in which the animals died at the end of a week, and in those which survived and were killed a month later. Antitoxin given early and in sufficient dose prevented the myocarditis after the injection of toxin in any amount.

The author believes from this that large doses of antitoxin given early will do away with all cardiac complications of diphtheria, and also, from still another series of experiments, with postdiphtheritic cachexia as well. He says that from 4,000 to 6,000 units should be given at a time and repeated frequently, and that when this is not promptly effective as much as 20,000 to 50,000 units should be administered intravenously. For this purpose one must be sure that the antitoxin is sterile, and is free of any preservative. This advocacy of the large doses of antitoxin is quite in accord with the work of McCallum and others in this country, who some ten years ago advised giving enormous quantities in all cases of diphtheria. The work of Meyer is of especial interest as showing that, on the lower animals at least, the antitoxin has a decided protective action on the cardiac muscle, but that to produce its effect it must be given, not only early, but in large quantities. His point, too, that, when once the blood-pressure has fallen, antitoxin will not raise it, while suprarenal extract will, should, if promptly acted upon in severe cases of diphtheria with heart failure, prove to be a therapeutic aid of practical value.

HYSTERO-ORGANIC DISEASE.

This ailment, according to Babinski, is the outcome of a change in the form which hysteria has presented. It is no longer characterized, in many instances, by the major attacks, which we know. There is a curious alignment with, or development from, true organic diseases such as arthritis or neuritis. Consequently the practitioner finds his diagnostic craft high and dry on a reef of negative determinations.

Writing in the *Journal des Praticiens*, July 3, 1909, Babinski illustrates this difficulty as it appeared in the case of a young girl, for whose antecedent arthritis compression by plaster apparatus had been employed. She came for what looked like hydrarthrosis, but on examination the leg was found to be anesthetic, and had lost its function. It was at once seen that no hydrarthrosis existed. Either the trouble was a result of the compression, or it was hysteroid. Neuritis was excluded because the tendon reflexes were preserved, as well as the faradic response of the muscles. Rapid cure followed upon suggestion and forced (passive) movements. Electric treatment of ten minutes' duration was used from day to day. The coldness in the part and the swelling offered confusing evidence, but the treatment of the earlier arthritis by immobilization explained those symptoms.

Babinski attributes the singular manifestations of the hysterical patient in many cases to more or less unconscious suggestion by the physician himself, although many times they originate in the patient's mind. In this case, it arose from the feeling of

the patient that movement would cause distress. The immobilization contributed to the production of a local paretic state. Anesthesia resulted from the notion of the patient that, because movements were not felt, sensation was likewise impaired. Contractures would obviously be found.

Asking whether hysteria may be blamed for vascular disturbances, Babinski replies that the sequence of conditions is from primary organic changes to truly hysteroid vascular degeneration. This must not be assumed to mean that hysteria is passing; merely that the disease is taking on a form different from that of former times. The obscuration of any genuine case of organic disease with the development of hysteroid symptoms must be recognized, or the practitioner may wander in a blind path.

Deceit as a Therapeutic Measure.

It has been said that no man is competent to treat typhoid fever until he himself has had the disease. Though this is an exaggeration it is an aphorism of value and contains a nucleus of truth. Every physician who has suffered from a severe illness, particularly if it has been one in which his life was in imminent danger, ever afterwards not only takes special interest in that particular disease, but also has a closer understanding of the sufferings of his patients and a more acute appreciation of the significance of the symptoms. Yet it is the rare exception that a medical man writes of his own case. There seems to be an inherent modesty among the members of the profession which prevents them from publishing their own symptoms and thoughts during illness. Whether this is due to a feeling that describing one's own sufferings is a sign of weakness or cowardice, or to a natural desire to keep the *ego* out of scientific writings, it is a fact to be deplored. We cannot know too much of the subjective sensations of the patient. The layman is too often unable to describe them intelligently, and it is through the careful introspection and self-analysis of the ill physician that our knowledge in such matters must be obtained. It is therefore with especial interest that we read in the *Deutsche medizinische Wochenschrift* for June 17, 1909, an account by Richard Lehmann of Berlin of a severe attack of appendicitis with perforation and general peritonitis from which he himself suffered a few months ago. Following two mild attacks the previous year, neither of which lasted more than two days, the writer was taken ill with what appeared to be a third of equal insignificance. After a few hours, during which he was scarcely ill, on turning over in bed he was taken suddenly with terrific pain, rigidity, and collapse, and an immediate operation revealed a gangrenous perforated appendix and several ounces of free pus. General peritonitis and obstruction requiring colostomy followed, and for several days but little hope was entertained for his recovery. During this time he was conscious, and, though himself fully appreciating his critical condition, demanded of the surgeon the truth as to whether or not he would recover. The surgeon assured him that he would soon be well. Though the patient knew that he had a general peritonitis, and that the surgeon could have no such hope as his words suggested, this reply gave him great comfort and mental relief. The main lesson that Lehmann drew from his illness was the fact that no matter how much a patient demands the truth, no matter how much he thinks he wants it, when he is seriously ill what he really desires is to be deceived. Although he knew that the surgeon was lying, the lie gave comfort and peace of mind. Those of us who have been in the same situation can well appreciate the truth of this statement and can remember with gratitude the confidence inspired by the cool, assuring, if not quite truthful, words of the medical adviser. Whether it is right deliberately to deceive a patient or any one else under any circumstances we must leave to the casuists and specialists in ethics. We simply record the facts as they are.

A Modification of the Esbach Test.

The well known method for the quantitative estimation of albumin devised by Esbach some years ago, though hardly of sufficient accuracy for scientific work, is so simple and so easily carried out that it has come to be used almost universally for the clinical estimation of the quantity of albumin in the urine. The great drawback has always been the necessity of waiting twenty-four hours for complete precipitation before reading the results. Working to overcome this Kwilecki has devised a simple modification, which he describes in the *Münchener medizinische Wochenschrift* for June 29, 1909, by means of which he claims to be able to estimate small quantities of albumin in two minutes and larger amounts in from five to six minutes. The method differs from Esbach's simply in the addition of ten drops of a ten per cent. ferric chloride solution to the measured amount of urine after it is put in the tube and before the Esbach's solution is added, and after gentle mixing placing the tube in a water bath at a temperature of 72° C. The precipitation begins almost immediately and is complete in a few minutes, when the results are read in the usual manner. This method is but slightly more complicated than the usual Esbach estimation, and, as it saves twenty-four hours, should, if it proves to be accurate, be a modification of value in saving much annoying delay.

News of the Week.

Work of Infants' Welfare Committee of Chicago.—The plan of campaign of the Infants' Welfare Committee of Chicago has been determined upon, and as outlined in the Bulletin of the city Health Department will be as follows: (1) The United Charities Association will maintain at the various active centers a force of from eight to ten nurses, who will make a personal investigation of the conditions obtaining in the neighborhood where the death rate from diarrheal diseases among infants was high during the months of July, August, and September of last year. (2) The nurses from the Tuberculosis Institute during their daily work will take cognizance of any cases of the same kind and will report these to the United Charities Association. (3) The Department of Health contributes to this work by the appointment of ten physicians who will be assigned for three hours each day to the various stations of the Milk Commission of Chicago, the purpose being to examine children coming to those places for milk. They will advise as to proper feeding, dressing, treatment, and gen-

eral care of the children. (4) At two meetings held recently, at which most of the officers of the branch divisions of the Chicago Medical Society were present or were represented, it was decided unanimously that the Chicago Medical Society through its branches should cooperate with the Infants' Welfare Committee in furnishing to the indigent and deserving poor the necessary medical care and treatment, physicians to be furnished and appointed by the different branches for this purpose. The officers of the Chicago Homeopathic Medical Society, the Chicago Eclectic Society, and the Physio-Medical Society are to be asked to cooperate in a like manner. (5) A staff of physicians has also volunteered to appear at various places at such times as may be necessary to instruct parents and nurses in the proper care and feeding of infants. (6) All dispensaries, hospitals, nurseries, crêches, and children's open-air sanatoriums in the city of Chicago have been asked to join in this movement, and practically all of them have agreed to do so. With these united agencies working under an organized plan there is little doubt that the usual mortality among children from gastrointestinal diseases will be materially reduced.

Prize Milk Contests.—Contests in which milk dealers and producers will submit samples of their goods for analysis have been arranged for by the Detroit Board of Health. It is probable that the first one will be held about August 10. Prizes will be awarded for the best dairy products, several classes having been designated. The winners will be announced at a public meeting which will be addressed by milk experts of national prominence. The farms from which the samples are obtained will be visited by Government inspectors.

Cholera in Russia.—The Russian health authorities state that the cholera epidemic in St. Petersburg is well under control, and that they do not believe it will reach the proportions of the 1908 epidemic.

Pellagra in Illinois.—It is reported that there are now in the Dunning Insane Asylum at Dunning, Ill., three patients suffering from pellagra and that six others have recently died from the disease there.

Laboratory Diphtheria.—The city chemist of Milwaukee has been suffering from an attack of diphtheria, supposed to have been contracted from working with cultures of the diphtheria bacillus in the laboratory of the Health Department.

The New York City Death Rate for the week ending July 17 remained low, 15.97 as compared with 18.48 for the corresponding week last year. This year there were 1,397 deaths as compared to 1,567 last year.

Cocaine Seller Arrested.—A man was arrested in the street in New York recently for selling cocaine. Over $100 worth of the drug was found on the man at the time. He was peddling it at a rate which would give him a profit of about $25 an ounce.

Dr. H. B. Ward, formerly dean of the College of Medicine and Professor of Zoology in the University of Nebraska, has accepted the position of Professor of Zoology at the University of Illinois, Champaign, to succeed Professor Stephen A. Forbes.

Dr. August Hoch of the Bloomingdale Hospital at White Plains has been appointed Director of the Pathological Institute at Ward's Island, New York, to succeed Dr. Adolph Meyer, who has been appointed Director of the Phipps Psychiatric Institute.

College of Medicine, University of Nebraska.—Plans have been drawn for a group of buildings to be erected for the College of Medicine, University of Nebraska. The group will comprise a central building with four wings for a general hospital, four corner buildings, each in the shape of an "L," for the orthopedic hospital, child saving institute, women's hospital and laboratory, and smaller buildings for administration and special laboratory between the corner buildings, the whole making ten buildings and forming a quadrangle.

Hospital at Ellis Island.—The deficiency bill passed by the House of Representatives in Washington, July 20, carries an appropriation of $20,000 to equip the contagious disease hospital at the Ellis Island immigrant station at New York.

New Hospital at Green Bay, Wis.—A new hospital has been opened at Green Bay. It is established by the Methodist Church and is to be in charge of deaconesses.

Home for Blind Babies in New Jersey.—The International Sunshine Branch for the Blind expects to found a home in New Jersey for blind babies. The Arthur Home property in Pine Grove Avenue, Summit, N. J., has been presented to the society for the purpose.

The Public Health Education Committee, a new organization of women physicians, has just been formed, its object being to instruct the laity in the prevention of disease. Dr. Rosalie Slaughter Morton is chairman of the Executive Committee. Dr. Sarah R. Adamson Dolley of Rochester has been made honorary chairman of the body. The secretary of the Executive Committee is Dr. Evelyn Garrigue of 616 Madison Avenue, New York.

The New York Italian Medical Society has been incorporated recently. The objects of the organization are "to maintain professional decorum and standard among its members and among other members of the medical profession, and particularly those who are Italians or Italian-Americans."

The Fourth International Congress of the Medical Press will meet this year at Budapest on August 27 and 28, on the eve of the Sixteenth International Congress of Medicine, and under the presidency of Professor Posner of Berlin. The sittings will be held in the Palace of the Academy of Sciences (Akademia utcza 2, Budapest V.), where the assembly hall has been placed at the disposal of the International Congress of Medicine. For this congress, to which all members of the medical press will be admitted, no entrance fee or subscription will be charged. The only condition of admission is that of being also enrolled as a full member of the International Congress of Medicine. Demands for admission should be sent before August 1 to the general secretary of the International Association of the Medical Press, Dr. Raoul Blondel, 103, Boulevard Haussmann, Paris.

The International Antialcoholic Congress, which has been in session in London, has accepted the invitation of Queen Wilhelmina of the Netherlands to hold the next congress at The Hague in 1911.

The Tristate Medical Association, which met in Toledo July 13, elected the following officers: *President,* Dr. C. B. De Nancrede of Ann Arbor, Mich.; *Vice-President,* Dr. Joseph A. Duncan of

Toledo; *Secretary,* Dr. George W. Spahn of Elkhart, Ind., and *Treasurer,* Dr. J. A. Weitz of Montpelier, Ohio.

The West Virginia State Board of Health recently elected the following officers: *President,* Dr. J. L. Dickey of Wheeling, and *Secretary,* Dr. H. A. Barbee of Point Pleasant.

The Rhode Island Medico Legal Society has elected the following officers: *President,* Mr. George H. Huddy, Jr. of Providence; *Vice-President,* Dr. Donald Churchill; *Secretary and Treasurer,* Dr. C. R. Doten; *Board of Censors,* Coroner C. H. Lincoln of Providence, Dr. Stimson of Tiverton, Dr. C. S. Christie of Riverpoint, Dr. J. Howard Morgan of Westerly, and Dr. C. W. Stewart of Newport.

Memorial Tablet to Dr. Wightman.—The members of the class at the Cooper Medical College, of which the late Dr. W. M. Wightman was a member, propose erecting a tablet in his memory. Dr. Wightman was a Passed Assistant Surgeon in the U. S. Public Health and Marine Hospital Service. While on duty at Guayaquil, Ecuador, he contracted yellow fever and died.

Obituary Notes.—Dr. M. A. Atkinson of Eureka Springs, Ark., died on July 14, aged 62 years. He was a graduate of the College of Physicians and Surgeons of Keokuk, Iowa, in 1872.

Dr. Arthur Earl Beach of Carroll, Iowa, died suddenly at his home on July 13, aged 35 years. He was a member of the Carroll County Medical Society and Iowa State Medical Association. Dr. Beach was a graduate of the Northwestern University Medical School of Chicago in 1905.

Dr. Joseph M. Emmert of Atlantic, Iowa, died at his home on July 14, aged 63 years. He was a graduate of the Jefferson Medical College of Philadelphia in 1872, and was a member of the Cass County Medical Society, the Iowa State Medical Association, and the American Medical Association. He was also the founder and first president of the Botna Valley Medical Society. From 1892 to 1898 Dr. Emmert was a member of the Iowa State Board of Health, and in 1898 he was elected to a seat in the Iowa State Senate. He was a member of the State Board of Parole and Pardons.

Dr. James Evans of Florence, S. C., died on July 14, at Clifton Springs, N. Y., aged 79 years. He was a graduate of the Medical College of Pennsylvania. On graduation Dr. Evans entered the army as a surgeon, and served through the Civil War. For many years he was secretary of the South Carolina State Board of Health, from which position he resigned in 1907. Dr. Evans was an extensive writer, especially of popular works on the hygiene of children. He was a member of the Florence County Medical Society and the South Carolina Medical Association.

Dr. W. E. Moore of Derby, Iowa, died at Lincoln, Nebraska, on July 8, aged 57 years. He was a graduate of the College of Physicians and Surgeons of Baltimore in 1881, and was a member of the Lucas County Medical Society, and the Iowa and American Medical Associations.

Dr. John C. Pannonborg of Hammond, Ind., died at his home on July 9, 1909, after a long illness, aged 54 years. Dr. Pannonborg was born in Germany, but came to America at the age of eleven, and later received his medical education at the University of Louisville. He was a member of the Lake County Medical Society, and the Indiana and American Medical Associations.

Dr. Clair S. Parkhill of Hornell, N. Y., died at his home July 20, 1909, aged 65 years. He was a graduate of the Albany Medical College in 1866, was a member of the Steuben County Medical Society, the New York State and American Medical Associations, the president of the Erie Railroad Surgeons' Association, and one of the most prominent physicians of Steuben County.

Dr. Joseph Robbins of Quincy, Ill., died on July 19, aged 75 years. He was a graduate of the Jefferson Medical College of Philadelphia in 1861, and was for many years superintendent of the Central Hospital for the Insane, in Jacksonville, Ill. He was a member of the Adams County Medical Society, and the Illinois State Medical Association. Dr. Robbins was prominent in State politics at one time, having been presented to the State convention as a candidate for the Governorship of Illinois.

Dr. Aaron Condit Ward of Orange, N. J., died at Nauheim, Germany, on July 19, 1909, aged 48 years. He was a graduate of Princeton University in 1883, and of the College of Physicians and Surgeons of New York in 1886. Dr. Ward engaged in the practice of medicine in Newark, N. J., until five years ago, when he gave it up to devote his entire time to the Prudential Life Insurance Company, of which he was a medical director.

Dr. James B. Cowan of Tullahoma, Tenn., died suddenly of heart disease, at his home, on July 24, aged 77 years. He was a graduate of the Medical Department of the University of the City of New York in the class of 1855. Dr. Cowan served through the entire Civil War as chief surgeon on the staff of General Forrest of the Confederate army. He practised for many years in Tullahoma, and was a member of the County and State Medical Societies.

Dr. Charles O. Hunt of Portland, Maine, died suddenly of heart disease in the Scarboro Beach Station on July 24, 1909, at the age of 70 years. Dr. Hunt was a graduate of the University of Pennsylvania in 1868, a Civil War veteran, a member of the Cumberland County Medical Society, and the Maine Medical Association.

Dr. Cyrus Francis Krauser of New York died on July 9, 1909. He was graduated from the Long Island College Hospital in 1867.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL TOUR, HOSPITALS AND UNIVERSITIES—LEAGUE OF MERCY—FUTURE OF TROPICAL MEDICINE—ELECTROLYSIS AND BACTERIA—POOR LAW DOCTORS' ASSOCIATION—THE LATE DR. LALCACA.

London, July 9, 1909.

Unseasonable weather has done much to mar the royal tour in the northern and midland counties, but their Majesties seem to have met it cheerfully and the program was punctually carried out. On Tuesday the new buildings of the Manchester Royal Infirmary were opened by the King, who, with the Queen, arrived during a heavy downfall. It was a public holiday, but the enthusiasm of the people was unabated by the rain. At the university a halt was made and an address presented, to which the King replied and expressed his pleasure that the cause of learning and research in Manchester is united with that of practical benevolence by fortunate alliance with the great hospital. The Royal Infirmary dates from 1752 and after a long and distinguished career in the city is now being transferred to a more open site outside. The new buildings are constructed to accommodate 600 patients, but at first will be equipped for 483. The estimated cost is £500,000, of which £400,000 is provided by the sale to the city corporation of the old building.

With the due ceremony of these occasions the new infirmary was declared open by His Majesty. Afterward the King, Queen, and Princess Victoria visited two of the wards and unveiled their name plates. Their Majesties also spoke a few words to the patients in these wards—named after themselves, King Edward VII. and Queen Alexandra wards.

The next day the royal party left Knowsley, where they had been staying with Lord Derby, and drove in a motor to Liverpool—a distance of six miles thronged with cheering crowds. At the station an address was presented by the Lord Mayor and briefly responded to. The special train was then taken for Birmingham, where the King was to open the new university. Great preparations had been made for the occasion and the whole route traversed by the procession was decorated with Venetian masts and flags. There were also a number of arches constructed so as to illustrate the municipal enterprise and the chief trades of the city. At the Council House there was another address and full ceremony, but I must pass on to the university, where the great function of the day took place. Here the King, replying to the address, expressed his regret that the Chancellor (Mr. Chamberlain) was prevented by illness from being present to witness the completion of the scheme so dear to his heart. Then His Majesty dwelt on the paramount importance of such institutions as this, where four faculties were at work and the citizens prepared to add others, so as to keep pace with all advances.

Yesterday, having concluded the provincial engagements and returned to town, the King, accompanied by the Queen, the Prince and Princess of Wales, and Princess Victoria, laid the foundation of the new buildings of the Imperial College of Science and Technology. The ceremony was performed with full pomp and circumstance in the presence of a brilliant assembly in which the robes of doctors of science set off the decorations by flowers and flags. The King spoke of the "supreme importance" of the highest specialized scientific instruction and research and of providing the fullest equipment for advanced teaching.

The Prince and Princess of Wales received the officials and members of the League of Mercy at a garden party to which more than 1,000 had accepted the invitation. The League has now been established ten years and has contributed to the King's Hospital Fund £116,000. The work is carried on by a network of about one hundred "districts," with some thirteen to fourteen hundred presidents, vice-presidents, and other officials and above twenty thousand members subscribing a shilling a year. None of the officials are paid and every shilling subscribed goes to the hospitals without any deduction whatever.

Professor Ronald Ross, in his presidential address, took an encouraging view of the future of tropical medicine, although the present state of things does not seem to give him satisfaction. He has long advocated the inclusion of parasitology and such subjects in the medical curriculum. The influence of disease on the decay of nations he thinks should receive more attention, and he holds that helminthiasis is largely responsible for the physical deterioration now so prevalent in tropical countries. He declared there was no reason why the tropics should not produce healthy, vigorous men, just as they did the strongest specimens of animals. The housing question is a burning one for the tropics, as much as for Europe. One or two advanced nations had shown the possibility of having cities without slums and he hoped the future would banish the miserable sights that were seen throughout the tropics.

The pressing objects were improvements in sewage and water supply, the better management and protection of wells, and the extinction of vermin. To achieve them sanitary organization must be completely remodeled. Some improvements had taken place, but further advances were imperative and the sanitary service of all the tropical colonies and possessions thoroughly organized. Judicious expenditure on this would pay from a monetary point of view.

Professor Ross then urged the members not to fall into the mistake of supposing that discovery, great or small, was the end of their duty as members of the Society of Tropical Medicine and Hygiene. Research, he said, was not a mere academical amusement and did not consist altogether in producing elegant articles adorned with colored plates. They had not only to teach, but to beseech, to demand and even to command. They must not take too haughty a view of their scientific work and stand apart from the throng of men for whom their work was done. It was for them to descend and go personally into the battle, to fight hand to hand in order to save their fellow men from grave and imminent dangers.

At the Royal Society on the 24th ult. Dr. Ch. Russ reported the results of a preliminary investigation which he had made to ascertain whether, during electrolysis of certain salts, suspended bacteria would pass to either electrode, with a view that if such were the case the fact might be employed for the detection of tubercle bacilli in the urine. He found that some bacteria under a suitable current did aggregate at one or other electrode. This aggregation varied with the electrolyte employed and might be due, perhaps, to affinity of the organisms for the products of electrolysis. The aggregation took place with dead as well as living bacteria, and the differences of behavior of different bacteria suggested to him that possibly this method might be utilized for specific discrimination. But as to this the data he had hitherto obtained were not sufficient to warrant a definite conclusion.

The annual meeting of the Poor Law Medical Association took place on Tuesday at the guild hall, when the Lord Mayor extended a kindly welcome to the members. Surgeon-General Evatt presided and lamented that there is no Minister of Health in England. Papers were read discussing the position of Poor Law medical officers in reference to the reports of the commission. Some approved the majority report, but others appeared to prefer that of the minority and there was a suggestion of cruelty made as to the latter. It was generally agreed that proper safeguards must be demanded for the profession as well as for the ratepayers. It was resolved that there ought to be a distinct service for the sick poor, so that they could be treated with economy but without pauperization. Surgeon-General Evatt was re-elected president and an invitation to meet at Halifax next year was received. At the dinner in the evening the president repeated his regret that there was not a Minister of Health in the Cabinet. Sir Walter Foster, Sir Dyce Duckworth, Sir Shirley Murphy, and many others took part.

The tragic death of Dr. Lalcaca in his attempt to prevent the murder of Sir Curzon Wyllie will be known to you. No doubt the particulars reached you as soon as they were known here. I will only say, therefore, that he was well known and highly esteemed here by a large circle of professional admirers and friends, who lament his untimely decease.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

TREATMENT OF GONOCOCCIC SEPTICEMIA—SUTURE OF VESSELS, TRANSPORTATION OF ORGANS, AND GRAFTS OF LIMBS—REACTION OF FIXATION IN THE DIAGNOSIS OF HYDATID CYSTS OF THE LIVER—DELAYED PSYCHIC TROUBLES FOLLOWING INJURIES OF THE SKULL—FULGURATION IN CANCER.

PARIS, July 10, 1909.

PROFESSOR DIEULAFOY gave a study of two cases of gonorrheal septicemia ending in cure and immediately followed by typhoid fever. Every individual attacked by gonorrhea, no matter how simple, may at any moment develop gonorrheal septicemia. Gonorrhea is not simply a local affection, but the gonoccus, once diffused in the blood, may produce various and very severe lesions. The most frequent localization of gonorrheal septicemic poison is in the joints and simulates articular rheumatism. Gonorrheal endocarditis almost always attacks the left heart, and the lesion is more frequently at the aortic than at the mitral orifice. The gonococcus likes the endocardium and produced in it ulcerative and vegetating lesions liable to create embolisms. Bronchopneumonia has been observed, and Dieulafoy cites a case observed by himself in which the gonococcus was found in the sputum. Gonococcic pleurisy is far from exceptional in the course of gonorrheal septicemia. The evolution of gonorrheal septicemia has a great resemblance to typhoid fever, and the differential diagnosis is extremely difficult; it should be made by cultures of the blood, which will show the gonococcus in pure culture, mixed with other microbes. In the patients mentioned by Dieulafoy the cultures had been made and had given positive results; the patients appeared quite well following subcutaneous injections of antigonococcic

vaccine, and Dieulafoy advises these injections in generalized gonorrheal septicemia.

Pozzi brought back from a trip to America, when he went to attend the Centenary of Ovariotomy, personal observations made by himself on the interesting work of Carrel. As a result of his work, suture of vessels has become a practical operation for the physiologist and surgeon. Surgical applications of this new knowledge are at present rare and hesitating, but the laboratory results are precise. Pozzi reports a case of grafting of the abdominal aorta with a piece of peritoneum in a dog of medium size, which lived two years after the operation and was in perfect health. The transplantation of fresh veins, which has been carried out in dogs, may be applied in surgery in the treatment of aneurysm.

Lejars and Parvu reported to the Surgical Society a reaction which seems destined to render great service in the diagnosis of hydatid cysts, which has been studied by Weinberg and practised by him. In five cases observed by the author indications have been made easy, and the conclusions have been verified four times by operation. In the presence of any visceral tumor the diagnosis of which is difficult to make by the usual methods of exploration, clinical and laboratory, this procedure is indicated. Unfortunately it involves a special technique.

Auvray has made a study of delayed psychic troubles following traumatisms of the skull, which show themselves under various forms—mania, hallucinations, tendency to suicide, delusions of persecution, and general paralysis. It is an undoubted fact that in a great many cases of dementia there are found at autopsy the traces of old traumatisms under the form of exostoses, sequestra, and meningitis. The interesting question is whether the mental troubles observed take their origin entirely from the traumatism, or whether the traumatism acts as an additional cause in a predisposed subject. Sebileau believes that the wound is generally a coincidence with the insanity, and that we should not accept the second as a consequence of the first. Quenu believes that the exclusive influence of traumatism in certain psychic states is undoubted. Delorme believes that the influence of traumatism on psychic troubles is considerable, but that it is necessary to take into account also other causes: syphilis, alcoholism, and individual predisposition. Picque believes that the traumatism produces diffuse lesions of the brain, prepares the soil, and creates circumscribed lesions: but, since the soil is only prepared by the lesions which the traumatisms cause, we may affirm that the latter create psychic troubles in all cases without its being necessary to invoke predisposition.

Nélaton reports a case of cancer of the rectum treated by fulguration, in which the action of fulguration has been nil, not to say bad. Quenu believes that it is necessary to operate first and apply fulguration after it. Sebileau has very little confidence in fulguration for cancer. Tuffier believes that fulguration has no pronounced action on cancerous tissue and that its action will not be effective at more than two milimeters depth; consequently its application is very limited. It is rather an agent of cicatrization than a destructive agent upon neoplastic tissues. Guinard thinks that we must make a wide operation of the cancer and then apply fulguration, for he has never seen any severe accident result from fulguration. Legueu has also convinced himself that the action of fulguration on cancer cells is nil, but that fulguration acts above all on the subjacent tissues. Fulguration appears to be a modifying agent for cancerous tissues in the same way as hot air, but without specific action, without curative action. Marion concludes that fulguration does not seem to aggravate the operative prognosis in point of view of large removals when they can be made. Ricard recognizes that fulguration has not lessened the limits of surgical interference, has not in any way ameliorated the cancer situation, and that inoperable cases still remain inoperable. Neither does fulguration lessen the liability to recurrence over surgical procedures. Jean Louis Faure has great confidence in the action of fulguration, and makes use of this procedure in all bad cases or even moderate cases, even though it seems to him to aggravate the operative diagnosis. Fulguration appears to have a sure and powerful action on the cicatrization of wounds, and he thinks that it should be extended to the treatment of all losses of substance rebellious to cicatrization. Schwartz has been struck by the rapidity of the cicatrical evolution of wounds following fulguration. He employs fulguration after taking care to remove surgically the largest possible amount of cancerous tissue from the entire region. Pozzi believes that the indications for the application of fulguration in cancer are very limited. On the other hand, he believes that fulguration should have an important application in the treatment of atonic wounds of various origin. Rochard thinks that fulguration as a method of treatment should not be rejected. Thanks to it, we can operate on and cicatrize cancerous wounds which were formerly considered inoperable.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 15, 1909.

Aural Complications in the Exanthemata.—Charles R. C. Borden emphasizes the following points: (1) In scarlet fever children are quite liable to middle ear inflammation, which may or may not involve the mastoid cells. Adults are much less so and rarely have mastoiditis. (2) In measles both adults and children are very susceptible to middle ear involvement and adults are especially in danger of mastoiditis. (3) In cases where there is a tremendous discharge present for more than two or three weeks the mastoid operation should be seriously considered as a means of providing drainage, other than through a small pin-hole perforation in the delicate membrana tympani. (4) Occasionally a case will arise in which the diagnosis may be difficult. If, after carefully ruling out every other possible cause by exclusion and the mastoid remains in doubt, and if the symptoms of the patient are at all serious, operate. The danger is greatest from waiting. (5) If, after the acute symptoms of scarlet fever and measles had subsided, pus in the middle ear is kept active by profuse nasal or nasopharyngeal discharges, examine the patient for adenoids. If the growths are present, remove them thoroughly. This procedure in the course of diphtheria, however, is questionable. (6) General practitioners should regard aural discharges as a menace to hearing and occasionally to life, and not as a more or less common complication without special importance. In a series of 1,164 cases previously reported by the author in children up to sixteen years of age, having aural diseases, 31.6 per cent. had chronic purulent otitis media of long standing.

Treatment of Chronic Suppurative Nasal Conditions by the Use of Lactic Acid Bacteria.—J. L. Goodale presents a brief summary of the results noted. The cases included conditions of atrophic rhinitis with ozena, and chronic suppuration of the various sinuses. From a study of the cases reported he believes that a distinct effect has been produced by the culture in some cases of ozena, characterized by general crust formation. The results appear to be comparable to those produced by argryol, which has hitherto seemed to be one of the most reliable applications. It remains, however, to be seen whether more than a temporary effect is produced. In localized chronic suppurative sinusitis, attended by hypertrophy and polyp formation, no effect could be detected. This negative result would naturally be expected in view of the extensive changes in the mucous membrane.

New York Medical Journal, July 17, 1909.

Diagnosis of Intestinal Tuberculosis.—Joseph Walsh presents a study on one hundred cases which came to autopsy in the Phipps Institute; they were in no way selected. The average age was thirty-one. Seventy-six showed ulceration of either the small or large intestine or both, and twenty-four no ulceration. In conclusions he says that (1) the symptoms, diarrhea, abdominal pain, tenderness, and rigidity, mean very little or nothing in the diagnosis of intestinal tuberculosis; (2) the presence of an ischiorectal abscess in an advanced case adds to the probability of intestinal ulceration; (3) the diagnosis of intestinal tuberculosis cannot be made with the slightest degree of certainty from our present known symptoms, and since the condition carries with it such an unfavorable prognosis, in order to reassure the patient, the nurse, and the physician himself, the diagnosis should not be made so that the patient will have a better chance for hopeful treatment.

Remissions in General Paralysis.—Morris J. Karpas makes this report. Two of the cases were tabetic and one was cerebral. Two were decidedly elated and

grandiose and one showed a definite depression, with general slowness in action and thought. Remissions lasted one year in one case, two years in the second and more than five months in the third. In no case were heredity or psychotic traits demonstrated; the remissions did not occur at the time of infection or suppuration. Syphilis could not be satisfactorily ascertained, but doubtless it could not be excluded. The disease picture, save for the remission, presented no anomalous traits and in each instance the diagnosis of general paralysis could be made without reservation. The question as to what are the probable factors which determine a remission in general paralysis is difficult to solve. Is it explainable on the peculiarity of metasyphilitic process? Or is it attributable to a special kind of bacterium paralyticum? These are purely theoretical speculations.

Pneumococcic Arthritis.—Alfred Strickler says that a study of the collected statistics shows that pneumococcic arthritis occurs once in about 800 cases of pneumonia. He reports the case of a Russian, twenty-five years of age, housewife, who was admitted to the hospital complaining of swelling and pain in the right knee and inability to walk. The family history was negative. Four months before admission she had pain in her right knee; the pain was dull in character, unattended with redness or swelling, but there was tenderness. The pain was worse on motion. She soon recovered. Two months previous to admission she gave birth to a child. Three weeks after her labor she again had pain in the right knee, with no redness nor swelling. The following day, however, the knee was red and swollen. On admission to the hospital the joint was tapped and six drachms of a reddish fluid was obtained. Examination of this fluid showed pneumococci in abundance. The physical examination revealed nothing abnormal except the knee, which was swollen, red, tender, and painful on motion. The temperature and pulse were normal throughout her illness, except for an attack of amygdalitis, during which febrile phenomena were present, but subsided rapidly after three days. Bier's treatment was resorted to for two hours daily, also evaporating lotions, with marked improvement. Later, passive motions, Scotch douches, and massage did the patient much good. She recovered from her arthritis, but some ankylosis resulted.

Journal of the American Medical Association, July 17, 1909.

Traumatic Neuroses.—The divergent opinions held by physicians and lawyers in regard to what are called traumatic neuroses are noticed by E. E. Gaver. Owing to the tangled condition thus caused, he thinks worthy persons often fail to get just compensation, while unworthy ones sometimes recover damages. While he does not believe that the German system of insurance against accident is a perfect solution of the problem involved, it is, he says, a great improvement over no system at all, as is the case here. The special features of the three cases he reports are as follows: The first was diagnosed as an organic case and operated on for brain abscess which was not found. Later it was diagnosed as a case of traumatic neurosis of the hysterical type, which it proved to be, and the patient recovered entirely, after obtaining damages from the city where the accident occurred. The second case was one of hysterical traumatic neurosis manifesting a rather fragmentary dissociation of personality, and the third was a temporary insanity from head injury, with former dissipation as a possible contributing factor. There are few cases of traumatic psychosis in which some such preceding factor, or heredity, can be absolutely excluded.

Underdeveloped Lower Jaw.—Two cases of underdeveloped lower jaw are reported by V. P. Blair of St. Louis. One of them, he believes, is unique in its pathology, and the procedures resorted to for their relief, advancing of the lower portion of the ramus to bring the teeth in better apposition and to allow a freer movement of the jaw and a wider opening of the mouth as well as improve the profile, have, so far as he knows, not been heretofore resorted to. In one of the cases a second operation had to be resorted to; a curved piece of cartilage one and a half inches long was taken from the eighth costal cartilage and inserted, to make up a bone deficiency. Some suppuration occurred, but the cartilage stayed in place, though the bony structures did not reform so satisfactorily as was desirable. Considerable dental prosthetic work was also done by Dr. F. A. Niehoff. The conditions are illustrated and the surgical history is an interesting one.

Ectropion and Entropion.—S. L. Ziegler recommends and describes a method which he has employed for many years with success in entropion and ectropion and some other conditions of the lids. It requires but two instruments which are figured, a short galvanocautery point and a lid clamp. He usually employs local anesthesia with 4 per cent. cocaine on the conjunctival surface, but in nervous, sensitive patients it is necessary to employ nitrous oxide, bromide of ethyl, chloroform, or ether. If ether is used it must be removed before the approach of the hot cautery point. The lid clamp is adjusted with its straight bar 6 mm. from the lid margin. The galvanocautery point is applied to the surface with considerable pressure. The button on the handle is pressed down to turn on the current, while the point is quickly pushed through the cartilage and as quickly withdrawn. The punctures are made 4 mm. from the lid margin and separated from each other by an equal interval of 4 mm. These should be made on the side on which we wish the contraction to take place, namely, the conjunctival surface in ectropia and the skin surface in entropion. If necessary we can repeat in a few weeks. From one to three sittings will accomplish as much as would a plastic operation. He has seldom seen any reaction follow, but if there is a little cellulitis and puffing of the lid the use of continuous ice-pads for a day or two will control it. Two or three repetitions are generally required, at intervals of from two to four weeks, according to the case. The procedure is perfectly under control. In repeating the operation it is well to alternate the punctures locating the second series between the first. The eschar of the cautery causes no disturbance and usually clears off in about a week. Fourteen cases are briefly reported, showing the effects of the procedure in the class of cases for which it is adapted. The article is illustrated.

Occupation Neuroses.—J. Madison Taylor gives his personal experience in the treatment of over forty cases of sensory and motor disabilities of the arm, due mostly to a neuritis. His object is to offer to practitioners measures which each one can readily apply and effect prompt and permanent cure. Success is largely dependent on the appreciation by the physician of the underlying condition, and the treatment in his cases was carried on along the lines of (1) constitutional regulations, using of drugs, etc., adapted from the interpretations of Dr. Sajous; (2) relief of psychic hypertension or misdirection by educative persuasion, relaxation of the whole organism, and teaching of economy in the expenditure of force; (3) quieting of the irritated vasomotor subcenters and improvement of their nutrition. The underlying conditions of neuritis are due chiefly to agencies affecting the normal defensive power of the blood. There is often a history of previous constitutional disease which reduces the functions of the pituitary body, according to Sajous's teaching, which Taylor follows. The phenomena are usually those of hypocatabolism, acidosis, and autointoxication. Among the exciting causes the most common is cold, especially when one is exhausted, and also infectious disease. The measures to be taken against these factors are drugs causing vasodilatation, such as the bromides and chloral; drugs that cause vasoconstriction by stimulating the sympathetic centers, such as morphine, atropin, etc., and local remedies causing local reflex vasoconstriction; measures which directly deplete perineural arterioles, such as venesection, cupping, and hot applications, etc.; measures which tend to eliminate the causes of the neural congestion, such as laxatives and dietetic regulation, and lastly to combat the gouty state by stimulation of the adrenals. As regards the second point, relief of psychic hypertension, his experience is that the value of persuasion and educative measures cannot be underestimated in the treatment of these cases. He goes into detail in regard to the manual methods and manipulations and the importance of the physician's tactile dexterity in determining the degree of irritations and relieving them by frictions and pressure along the nerve courses. Stroking lymph channels with the affected nerve paths is, chronologically, one of the first of the indicated procedures. It should be performed centripetally and slowly, gradually increasing the pressure and taking about two minutes' time, and followed by squeezing of the entire limb from the extremity to the shoulder. He is enthusiastic as to the value of the application of judicious and graduated stretchings, along with torsion, which can only be safely done by the physician, gradually increasing the force until, after two or three weeks, the patient can stand a good deal

of force without marked discomfort. He thinks this is one of the most efficacious methods of relieving pain, aches, heaviness, and of restoring vigor. The re-education in coordination required should be carried on for months or years. After each passive treatment it is well to direct the patient to extend the arm and fingers with increasing force, and to hold the tension at the end of the act for three or four seconds, and to repeat the procedure, followed by rotation in various directions. This series of active movements should be insisted on for months, to be used three times a day. Occupation neuroses are generally the outcome of overuse of the arm in a flexed position, long maintained, and this kind of training in extension give the normal physiological relief.

Local Sweating.—Grover W. Wende and Frederick C. Busch report three cases of a peculiar sweat reflex which they have not found recorded in the literature. The fact, however, that after the first case was seen two others were met with would seem to indicate that the condition is not so rare as would appear from the lack of records. In all three cases the sweating either starts from a definite localized facial area or is confined to such. The reflex involved apparently includes on the afferent side the olfactory and possibly also the gustatory nerves, and on the efferent side the secretory fibers of the sweat glands of the face. Heredity is undoubtedly a factor in the causation, the condition having existed in one or more members of the family in one case for four generations and in the other two cases at least for two generations. In all cases the individuals are of a nervous type, with sensitive skin and mucous membrane. In the first case, tomatoes, strong tea, pickles, and roast beef brought on the reflex. In the second, onions was the cause, and in the third, pungent and peppery food as well as acids and condiments. In the first case the sweating began on the nose and forehead and spread to the whole face. In the second the infraorbital region only was affected. In the third, the region of the eyes, forehead, and upper lip. The authors offer the following conclusions: "1. Heredity is a decided factor in all these cases; in one the condition was traced through four generations. 2. The condition is not congenital, since it has not appeared in any of the cases before puberty. 3. Localization of the sweating is identical in all members of the same family. 4. The same stimuli produce the condition in all members of the family."

The Lancet, July 10, 1909.

Ionic Medication in the Treatment of Some Obstinate Cases of Pelvic Disease in Women.—Samuel Sloan says that ionic medication is the application of electrochemistry to therapeutics. All of the septic cases in which he has employed this treatment have done equally well, with the exception of one. What has impressed him during the practice of ionic medication has been the rapid improvement in cases of cervicitis. The discharge having been mucopurulent and copious has become milky and of small amount, while the gaping os has become normal in size, with the everted mucous membrane drawn in and erosions have rapidly healed. No case of hemorrhage has failed to yield at once to the treatment by ionic medication, with one exception. He has had only one case of bacteriuria in women which proved intractable. Since he began to treat pelvic affections by means of ionic medication he has treated fewer cases of septic endometritis by curettage, and he is satisfied from a long experience in the treatment of pelvic affections, inflammatory and septic, that in a large number of cases no other form of treatment will give results in any way approaching those to be obtained from ionic medication. A description of the solutions used, with pictures of the different electrodes, accompanies the article.

Spontaneous Cure of Thoracic Aneurysm.—Herbert S. French performed an autopsy upon a woman, seventy-four years old, who came under observation nine hours before her death suffering from acute dyspnea, associated with râles and rhonchi all over both lungs, and yet with so little available history that a precise diagnosis could not be made. She died apparently of acute edema of the lungs; at the post mortem it was found that she had typical granular kidneys, adherent pericardium, and a healed thoracic aneurysm. It was difficult to say for certain whether the aneurysm itself accelerated death, but had there been no aneurysm at all one would have been content, from the post-mortem appearances, to diagnose acute edema of the lungs, the result of atrophic red granular kidneys. The aneurysm was about the size of a tennis ball and was entirely filled with a hard, laminated, fibrinous clot, which was somewhat adherent to the wall of the sac and very hard. The contents of the sac came right up to the level of the wall of the aorta, so that the aneurysm could be truly said to have been spontaneously cured. The aneurysmal sac was partly within and partly without the pericardium, and it was adherent to both pleuræ, more especially the right. It did not obstruct either the right or left bronchus, the main pulmonary artery, nor the left pulmonary artery. It projected into the lumen of the right pulmonary artery, partly obstructing it.

An Unusual Case of Goiter.—H. Neville Crowe reports the case of a woman, fifty-four years old, who suffered from cellulitis of the neck and dyspnea due to a goiter the size of the clenched fist. The goiter was first noticed when she was seventeen years old and was treated with counterirritants until she was thirty-two, when she was admitted to the hospital, where she remained four months. The goiter was tapped and four fluid ounces of fluid were withdrawn, but a subsequent tapping a fortnight later was negative. Two weeks later tincture of iodine was injected into the substance of the growth, which produced much constitutional and local disturbance; when this had subsided a seton was introduced into the middle of the neck and remained *in situ* for five weeks. As this caused no diminution in the size of the swelling, she was advised to return home, as the case was incurable. Since leaving the hospital twenty-two years ago the sinus made by the seton has been continually discharging and she had been subject to what she describes as "shivering fits." These always came on in the morning, the patient feeling at first very cold and shivering, followed in about an hour by a profuse sweating stage with vomiting lasting a further hour, and then by forty-eight hours of extreme prostration. She stated that she had had as many as two of these attacks in a fortnight and they were worse just before her menstrual periods. She noticed that the attacks always came on when the discharge from the goiter ceased and were followed and relieved by a discharge of blood and pus from the sinus. Complete extirpation of the goiter brought about a radical cure. She has had no shivering fits since the operation.

British Medical Journal, July 10, 1909.

Treatment of Chronic Degenerative Lesions of the Heart and Aorta.—James Barr says that the ultimate causes of these degenerative lesions are frequently set down to toxins in the blood, but he has shown that at least in a large number of these cases there is an increase in the effete material in the blood as evidenced by the lower freezing point. Of all toxic conditions perhaps syphilis is the disease most frequently associated with these changes, and Dr. Bramwell thinks that it acts through the vasa vasorum, thus impairing the nutrition of the vessel. Among the other toxic agents he mentions typhoid fever, intestinal toxins, septicemia, influenza, gout, myxedema, diabetes, lead, ergot, and other pressor agents, as caffeine, theobromide, digitalis, adrenalin, purin bodies. The general opinion would seem to be that these toxic agents act directly on the walls of the aorta, producing the degenerative lesions, but it is his opinion that they act indirectly by raising and maintaining the blood-pressure at a high level, thus destroying the elasticity and impairing the nutrition of the vessel walls. Were it otherwise the pulmonary artery would be affected as often as the aorta, which is not the case. The dependent arteries of the lower extremities have a higher blood-pressure than in the upper extremities, and the former are usually much more affected with sclerotic changes than the latter. He then considers how this high blood-pressure in the aorta is maintained. If the systolic and diastolic pressures be both high, with a gentle gradient, you can depend upon it that the cardiac muscle is still fairly healthy and the aorta fairly elastic. You should therefore lessen their work by devoting your attention to the periphery. Vasomotor relaxants are here of not much value except as temporary expedients. If the patient have gouty kidneys, the purin bodies and other nitrogenous elements of food should be cut down and there should be a free administration of the benzoates. If there is too much lime in the system, all milk foods and jellies should be eliminated from the diet, and decalcifying agents should be freely used. The action of the skin should be encouraged and graduated exercises should be taken. With high systolic and moderate or low diastolic

pressure the elasticity of the aorta is becoming impaired. When there is a difference of 40 mm. of mercury it is high time to think of effecting repairs. The patient should be kept on a light, dry, nonstimulating diet, with little or no salt. Decalcifying agents as a rule are useful and moderate catharsis should be produced. When there is a high systolic and a low diastolic pressure, a dilated heart, and high intraventricular diastolic pressure, the diet should be dry and nitrogenous if the kidneys are healthy; the bowels should be kept open and a course of digitalis, squills, and nux vomica or strychnine is beneficial. These are not the cases for mountain climbing, but for moderate exercise on the level. When there is high systolic and low diastolic pressure, with aortic regurgitation, the result is largely influenced by the amount of elasticity left in the aorta. The diet should be light, dry, and nitrogenous, and the exercise should be moderate. A course of phosphorous acid and strychnine often answers well. When the systolic pressure is failing, with a relatively high diastolic pressure, the cardiac muscle is getting much impaired. In these cases the question of the free calcium ions in the blood must be considered. In such cases small doses of glycerophosphate of calcium and large doses of phosphoric acid are of benefit. When the systolic and diastolic pressures are failing and there is edema of the extremities, a temporary rest is highly beneficial. The diet should be light, dry, and nutritious, and nitrogenous if the kidneys be fairly healthy. Sodium chloride should be eliminated and a course of cardiac tonics prescribed. In many cases of myocarditis the right coronary artery is much more affected than the left. A good cardiac tonic in such cases consists of glycerophosphate of calcium, strychnine, and phosphoric acid.

Pain in Mucous Colitis and in Irritable States of the Colon in General.—T. Stacey Wilson speaks of a pain which seems to be usually due to a peculiar and hitherto little recognized form of muscular activity, which is associated with a varying degree of hardness of the bowel, combined with a varying amount of increase in its transverse diameter. This peculiar change is due to the development of abnormal tonic activity in the muscular coat. After explaining his theory of bowel tone he considers the etiology of bowel pain. Where the transverse colon is mainly involved the pain is more apt to be felt across the epigastrium above or below the level of the umbilicus, that is, directly over the bowel itself. A very common situation for the reference of colon pain is in the hips over the twelfth dorsal or the first four lumbar segment areas. Pain is very often referred to the sacrum over the situation commonly associated with uterine disturbance. It is very common for colon pain to be referred to the flanks or to the gastric area, or sometimes below the scapula, and to the lower dorsal segment areas. Sometimes colon pain is all referred to one spot 1½-2 inches across, just above the pubes; sometimes it is referred to a spot within the pelvis, between the base of the bladder and the obturator region. Sometimes it is referred to the region of the sciatic notch and sometimes down the leg even to the feet. Sometimes the pain is referred to a fixed spot over the upper lumbar vertebra. The pain arising in any part of the colon may therefore be all referred to some single skin area. When the upper part of the rectum is especially involved the pain is apt to be felt in the sacral region and it may be felt down the backs of the legs and even into the feet. The pain is very apt to occur in relation to the taking of food. It is not uncommon for the pain to come on before the meal is commenced. The pain may come on in relation to defecation. Or the pain may come on at irregular intervals without any definite relationship to the functional activity of the colon being traceable. Another characteristic of the pains resulting from irritation of the colon is the fact of its occurrence as the result of mechanical stimulation. These pains are greatly aggravated at the menstrual period.

Empyema Associated with the Bacillus Coli; Treatment by Antitoxin.—J. Sidney Pearson reports such a case occurring in a boy of seven years. Streptococci and *Bacillus coli* were found in the pus. Polyvalent antistreptococcic serum was given by the mouth and later anticolon serum was administered with excellent results. He has tried the anticolon serum in one case of acute gangrenous appendicitis, but without obvious result either before or after the operation; yet he believes that investigation in this direction is desirable. In no case was the antitoxin given hypodermically; children take the serum very well when administered with about double the quantity of warm milk. He has never known a dose to be vomited.

Berliner klinische Wochenschrift, June 28, 1909.

Observations on a Dog after Extirpation of the Duodenum.—Bickel reports some observations he has made on a dog from which he had resected the duodenum and sutured the gall duct and pancreatic duct to the abdominal wall, the pylorus being closed and a gastrojejunostomy made. The purpose of the experiment was to learn whether the secretion of bile and pancreatic juice which usually follows stimulation of the duodenum would also occur from stimulation of other parts of the intestinal canal. Ten minutes after 100 c.c. of olive oil had been put into the stomach a decided flow of both bile and pancreatic juice appeared. A profuse secretion of pancreatic juice, also, followed quickly upon the ingestion of hydrochloric acid into the stomach. It was therefore proven that stimulation of other parts of the intestine than the duodenum were able to cause secretion from the liver and pancreas. An interesting find at autopsy on this dog was the presence of several typical peptic ulcers in the jejunum. The author believes that the intestinal mucosa while resistant to ferments in an alkaline medium is unable to withstand digestion by an acid juice, a fact which has been shown by the autodigestion occurring in a section of intestine implanted into the stomach wall, and that the absence of the normal intestinal alkalinity due to the bile and pancreatic juice being emptied externally, accounted for the digestion of the jejunal wall by the acid gastric juice in the present case. He concludes that absence of the normal alkalinity in the intestines may be a cause, though not necessarily the only cause of peptic ulcers of the intestines.

The Influence of Radium Emanations on Metabolism in Man.—Silbergleit reports some experiments on two young adults in which he investigated the general metabolism by means of the Zunlz-Gebbert respiration apparatus. He studied the effect of drinking water containing from 5,000 to 50,000 units of "radium emanations." In both cases metabolic activity was distinctly increased.

Münchener medizinische Wochenschrift, June 22 and 29, 1909.

A Study of the Origin of Tumors of the Uterus.—Theilhaber has analysed 228 cases of myoma and 133 of carcinoma of the cervix, according to the social standing of the patients, and has found that myoma is much more common among the better classes, whereas carcinoma prevails more among the poor. He further shows that among Jewesses myoma is common and carcinoma very rare. He discusses fully the various conditions which predispose to myoma and carcinoma, as age, marital history, location of tumors, general nutrition of the patients, etc., and says that the predisposing cause behind the etiology of carcinoma is poor nourishment, either general or local. Myomata occur in the fat, carcinomata in the thin. Carcinomata are common in the cervix, the seat of scar tissue, while myomata are very rare there. Myomata occur during the active sexual life. Carcinomata at the age of atrophy of the uterus. Carcinomata of the urerine body are rare among young women, occurring only after many pregnancies, with their resultant scar formation, and consequent poor nutrition.

The Treatment of Skin Diseases by the Internal Use of Calcium Salts.—Bettmann refers to the good results reported from England of the use of calcium in diseases of the skin, and then reports his own experiences in treating 70 cases. He used a five per cent. aqueous solution of calcium lactate, giving one to two teaspoonfuls thrice daily, one hour before meals. In many cases he got no results. One case of purpura which had withstood all treatment for two years, recovered in four weeks and remained well. Two cases of long standing urticaria recovered promptly. A case of angioneurotic edema failed to respond. Several cases of pruritus senilis recovered quickly. In localized pruritus, especially pruritus genitalis, good results were obtained. In three children with prurigo and others with lichen strophulus quick recovery occurred. One case of herpes gestationis in which the patient in two previous pregnancies had suffered until the end of pregnancy cleared up after four weeks calcium lactate treatment. The treatment was also tried in eczema, lichen ruber, chronic herpes, pemphagus, etc., without results. The author concludes that we cannot place much reliance on calcium lactate as a therapeutic agent; we cannot state any one disease which it will cure with regularity. On the other hand very striking results may be obtained in isolated cases.

Serum Treatment of Epidemic Meningitis.—Bruno Leick reports his results in treating cerebrospinal menin-

gitis with the Kolle-Wassermann serum. In sixty-two cases treated without serum or with the serum subcutaneously twenty recovered, a mortality of 67.7 per cent. The cases treated with the serum were diagnosed bacteriologically with the exception of three in whom the organisms could not be found. Of the thirty-four cases treated with the serum, eleven died, a mortality of 32.4 per cent. Of these five were moribund when treated. Disconsidering these there were twenty-nine cases with six deaths, a mortality of 20.7 per cent. In most of the recovery cases the recovery was complete. Once there was deafness; once partial deafness. One nine-year-old boy had a partial hemiplegia, and one of four and a half years was left mentally deficient. The author concludes that the serum is of great value, that the mortality was reduced from 67.7 per cent. to 20.7 per cent., and that the serum is without danger.

A Case of Tumor of the Liver with Levulosuria.—L. Borchardt states that it has been shown that levulose is made into glycogen exclusively in the liver, whereas dextrose is converted in the muscles as well. Nevertheless no case of spontaneous levulosuria had been reported in connection with gross liver disease. He then reports a case of a woman of 44 years of age, who in association with a rapidly growing hepatic tumor had a constant levulosuria. The urine was studied carefully for two weeks. There was an increase of the ammonia quotient, urobilinuria, and albuminuria, as signs of hepatic insufficiency, and constant levulosuria. The ingestion of levulose increased the levulosuria while dextrose did not effect it. There was no autopsy.

The Bacterial Content of Normal Organs.—Conradi has devised a method of taking cultures from organs which makes contaminations most unlikely. The tissue in pieces of about 50 grams weight are cut from the organ immediately after death with sterile instruments. These are dipped for from one-half to one minute in oil heated to 200° C. and then placed for four hours in a 2 per cent. bichloride solution. Then they are placed in sterile dishes, of which the covers are made air tight by means of wax, and the dishes placed in the thermostat for twenty hours at 37° C. The pieces of tissue are then cut in two and the central portions removed. These are cultivated both anaërobically and aërobically. The author investigated by this method 162 pieces of tissue taken from 150 animals, oxen, cows, calves, and pigs. The animals were all well nourished and had been to all appearances healthy. From 72 of the 162 specimens organisms were grown. They were most commonly found in the liver, namely, in 42 out of 63 cases. Of 59 pieces of muscle 18 contained organisms; of 19 pieces of kidney, 6; of 5 lungs, 4; of 4 lymph glands, 1; and of 11 spleens, 1. The aërobic organisms identified were *B. coli communis, B. lactis aërogenes, Streptococcus acidi lacti, B. mesentericus, B. fluorescens non liquefaciens, Diplococcus pneumoniæ Fraenkel and B. suipestiferus.* The hog cholera bacilli were found in healthy animals. Anaërobic organisms were common. Of the 72 positive cases 30 were anaërobic.

The Significance of Intraperitoneal Hemorrhage in Penetrating Wounds of the Intestines.—Gutzeit reports a case of traumatic rupture of the intestines and concludes from his findings that in cases of injury to the intestines the hemorrhage is more rapid than the extravasation of intestinal contents, and that the blood may wall off the peritonitis and prevent a general infection. On the other hand, the abdominal spasm, the distention and paralysis of the gut due to the peritonitis may, by increasing the intra-abdominal pressure, control the hemorrhage. In this way each condition assists in controlling the other.

The Moro Reaction.—Bullinger describes his experience with Moro's reaction with tuberculin ointment. He used 5 c.c. old tuberculin in 5 gm. anhydric lanoline. The patients varied from 16 to 65 years of age. His results were as follows: In 48 cases of suspected tuberculosis, 35 were positive and 13 negative. In 19 cases of first and second stage tuberculosis 15 were positive and 4 negative. In 6 cases in the third stage 1 was positive and 5 negative. In 11 cases supposedly tuberculosis free, 1 was positive and 10 negative. He concludes that the reaction is a valuable aid in the diagnosis of early tuberculosis, that its use is simple, even for the practising physician, and that the course of the reaction is harmless and in general not disagreeable to the patient.

Deutsche medizinische Wochenschrift, June 24 and July 1, 1909.

Infantile Tabes in a Ten-Year-Old Girl.—R. Halben reports this case. The child of 10 years had been under observation for some time without showing any nervous symptoms. Then he noticed bilateral loss of pupil reaction to both light and convergence. There was loss of patellar reflex, some impairment of pain and temperature sensation, but no anesthetic zones. No Romberg symptoms, no ataxia. Vision normal. There were no other signs of tabes or syphilis. The father had progressive paralysis; the mother had died of tabes dorsalis. The Wassermann reaction was doubtful.

Estimation of Proteolytic Ferments in the Stools.—Döblin has applied the casein method of estimating pepsin to the stools. His method is as follows: The fresh stool is mixed with an equal amount of water, filtered and preserved with an equal volume of glycerin. The casein solution is made by dissolving, with gentle warming, 0.5 casein in 10 c.c. of water to which a drop of 10 per cent. sodium carbonate solution has been added and the solution raised to 500 c.c. with water. A few drops of xylol is added to preserve it. It will keep at most three days. The purpose of the test is to find how much of the stool solution is required to digest 5 c.c. of the casein solution in six hours at a temperature of 37° C. In each of ten tubes is put 5 c.c. of the casein solution and amounts of the stool extract varying from 0.1 to 5.0 c.c. To each tube is then added distilled water to 10 c.c. After six hours in the thermostat the tubes are examined to see in which the casein has been digested. The author found that in infants' stools the ferment was in many times greater amounts than in the adults. The method is still far from perfect for clinical use.

A New Method of Exact Estimation of Tubercle Bacilli for Injection Experiment.—Rabinowitsch summarizes his results as follows: (1) The mass of bacteria is allowed to stand for twenty-four hours in a thermostat at 37° to 40° C., in which is placed a glass of water to insure a constant moisture. (2) After twenty-four hours the desired amount is weighed on the chemical scales and injected directly into the animal.

Percussion in Pleural Effusion.—Gantz discusses the accepted ideas as to the percussion line of dullness along the upper border of pleural effusions with especial reference to the paravertebral triangle of Grocco. He concludes from examination of a large number of cases that: (1) the highest point of dullness is not at the vertebra but at the angle of the scapula; that (2) from this point the line of dullness falls steeply to the spinal column, making a triangle with its base upwards, and more gradually forward; and (3) in this triangle the percussion note is clearer than over the fluid, sometimes even tympanitic.

The Question of Intestinal Pneumonoconiosis.—Tsunoda discusses the literature of the work which has been done to show that pneumonoconiosis is due to absorption of dust, etc., from the gastrointestinal tract, and not to direct inhalation. He then describes a series of experiments on rabbits in which he put emulsion of ink into the stomach by means of a stomach tube. His experiments were in three series, according to whether the ink was given in one large dose, in small doses over several weeks, or into the fasting stomach. In none of his rabbits did he find that the ink had reached the lungs. In only a few was there a slight pigmentation of the mesenteric lymph glands. He concludes that from his studies he has proved that the mechanism which regulates the occurrence of pneumonoconiosis is in no way analogous to the theory of Behring and Calmette that pulmonary tuberculosis is of digestive origin.

The Provocative Action of Bichloride on Syphilis.—Buschke and Harder show by the study of a series of patients that a single large dose of mercury given to a patient in the first stage of syphilis will often precipitate the appearance of secondary symptoms. They examined in all 46 cases, and obtained this reaction to mercury in 20 of them. The reaction occurs only towards the end of the second incubation period. They tried to find some constant relationship between this phenomenon and the Wassermann reaction, but were unable to do so.

Dyspnea Following Nasal Installation of Menthol Oil.—A. Delille, in a paper read before the Société de Pédiatrie in Paris reported the case of an infant in whom a nasal instillation of menthol oil, 1 per cent., was immediately followed by violent spasm of the glottis. After fifteen minutes the child recovered. Guinon had observed several similar cases. Marfan had never seen one. Comby thought 1 per cent. was too strong. He used menthol oil 1-300.—*The British Journal of Children's Diseases.*

Book Reviews.

The Elements of Hygiene for Schools. Compiled by Isabel McIsaac, late Superintendent of the Illinois Training School for Nurses; Collaborator of the "American Journal of Nursing"; Author of "Primary Nursing Technique" and "Hygiene for Nurses." New York: The Macmillan Company, 1909.

By far the greater part of this book is a reprint of the same author's work on Hygiene for Nurses, noticed in the Medical Record of December 12, 1908. Fortunately, the pages on "the duties of medical inspection of schools" are omitted, but a new chapter on bacteria is here included, and the author tells us that the time is fast coming when a textbook, and not a single chapter, will be devoted to bacteriology in all schools. The book is well written, but much of it will prove to be beyond the class for which it is avowedly intended.

A Manual of Practical *X*-Ray Work. By David Arthur, M.D., D.P.H., Medical Officer in Charge of *X*-Ray Department, West London Hospital, and Lecturer on Radiology, West London Post-Graduate College; and John Muir, B.Sc., M.B., Ch.B. and B.Sc. (Pub. Health). With about 120 illustrations. New York: Rebman Company, 1909.

This book is intended for readers who want a practical understanding of radiology with just sufficient detail to enable them to operate an ordinary installation. Considerable space has been devoted to apparatus, but the principles of construction have been emphasizel rather than details which are likely to vary. So, too, the care and working of accumulators and of induction coils are described quite fully. With the aid of this small volume the worker will obtain a knowledge of the apparatus required, the methods and detail of its operation, and a help to an intelligent interpretation of the finished radiogram. The work is a practical manual based on the personal experience of the authors, and is likely to be very useful. The arrangement, print, illustrations, and general get-up of the book are all excellent.

Infant Feeding. By J. S. Fowler, M.D., F.R.C.P.Ed., Physician to the Royal Hospital for Sick Children, Edinburgh; Joint Clinical Lecturer on Diseases of Children, University of Edinburgh. London: Oxford University Press, 1909.

This little book is a practical guide to the feeding of infants in health and disease. It is well written, and gives in clear terms the essentials of the various methods in use, frequently going into details where these are of importance. While naturally laying especial emphasis on the author's favorite methods, it also gives clearly the American percentage method, the German calorie method, and the Budin system, and is exceptional among works on the subject in being fair to all. An appendix gives the composition of the commoner infant foods, and of the various animal milks, schedules for feeding, recipes, and percentage feeding tables. It is well printed, in clear type, on heavy paper. This little book is sure to be well received by those who want directions for the ordinary care and feeding of infants. If printed with a slightly smaller type, on thinner paper, it would make an ideal pocket manual of infant feeding.

Surgery: Its Principles and Practice. By Various Authors. Edited by William Williams Keen, M.D., LL.D., Emeritus Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia, and John Chalmers DaCosta, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume IV. With 582 illustrations, 22 of them in colors. Philadelphia and London: W. B. Saunders Company, 1908.

The fourth volume of this system is devoted to a series of subjects comprising some of the most important in the whole domain of surgery, and its excellence is evidence of the merit of the entire work. Among the topics discussed are hernia, rectal surgery, the surgery of the entire genitourinary system, surgery of the intestines, surgery of the eye and ear, military surgery, naval surgery, tropical surgery, and the influence of race, sex, and age in surgical affections. One of the most important chapters from the practical standpoint is that by Dr. David L. Edsall on the examination of the urine in relation to surgical measures, in which the true value of the more elaborate laboratory methods is clearly explained and some prevalent misconceptions as to the diagnostic infallibility of many of them are pointed out. The passages relative to the subject of urea determinations as ordinarily carried out are especially to be commended to those still under the ban of this fetish. Other chapters of more than usual interest are those on military and naval surgery, by Surgeon-General Robert M. O'Reilly, U.S.A., and Surgeon-General P. M. Rixey, U.S.N., respectively, in which the material offered by the various recent wars has been fully utilized in elaborating new principles and methods for future application.

Atlas and Epitome of External Diseases of the Eye. By Professor Dr. O. Haab, of Zurich. Edited, with additions, by Geogre E. de Schweinitz, M.D., Professor of Ophthalmology, University of Pennsylvania. Third Revised Edition. Philadelphia and London: W. B. Saunders Company, 1909.

This edition of Haab's Atlas, like its predecessors, presents the subject in a thoroughly up-to-date manner. The numerous and excellent colored plates, presenting as they do, a very true representation of the actual conditions, cannot fail to be attractive, instructive, and very valuable to the student of diseases of the eye. Some addition to the text and a few new colored plates have been included in the new edition of this work.

Life's Day. Guideposts and Danger Signals in Health. By William Seaman Bainbridge, A.M., M.D. New York: F. A. Stokes Company, 1909.

This is another volume in what one may call "The Twentieth Century Life Series." The interest of the public in the problems of health and disease seems to be on the increase if the wide reading of works such as this may be taken as an index. There is, of course, no denying the need for such books in cultivating a wholesome optimism in these strenuous times in which we live. They are likely to do no harm, and may accomplish a great good. Dr. Bainbridge's volume is based on a series of lectures which he has been giving each summer at Chautauqua. They are philosophic rather than dogmatic, and serve to show how the basic principles of heredity, environment, and function interact upon the individual for good or ill according as he does or does not cultivate a proper attitude toward external things. The author considers his subject under the various headings of Dawn, Morning, Midday, Twilight, and Night, and has something helpful to say of each of these periods of life. He has drawn largely from all sources, ancient and modern, and his brilliant vivacious style makes the book thoroughly readable.

Thérapeutique Médicale et Médecine Journalière. Par G. Lemoine, Professeur de Clinique Médicale à la Faculté de Médecine et de Pharmacie de Lille, Médecin de l'Hôpital Saint-Sauveur. Cinquième Édition. Paris: Vigot Frères, 1909.

This book is of great practical usefulness. The author gives a satisfactory résumé of every common disease seen in daily practice, and then proceeds to discuss the various methods of treatment in detail, exhibiting finally that which has served him best. The volume is, therefore, an exhaustive *vade mecum* on internal medicine. Clinical considerations hold a prominent place throughout, the author confessing the desire to make, not a work of science, but something useful to those who are lost in the great detail by which therapeutics is encumbered, and who desire to know the clinical indications for those means which they employ. A great number of formulæ are given, chosen from among many for their utility and ease of administration. Electrical methods of treatment receive special mention, but only those which the author himself has used. He believes that physical agents have an important place in therapy, and that proper knowledge of them is indispensable to the practitioner. Dr. Lemoine's book is an extremely valuable one to all internists, moreover it is interesting to read.

Die wichtigsten Bakterientypen der Darmflora beim Säugling, ihre gegenseitigen Beziehungen und ihre Abhängigkeit von äusseren Einflüssen. Von Dr. Paul Sittler, Privatdocent für Kinderheilkunde an der Universität Marburg. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1909.

The writer has investigated the manner in which the various types of bacteria find their way into the intestinal tract of the infant and their subsequent growth. He finds that there is a considerable difference between the flora of the upper and the lower portions of the alimentary canal; and that the first infection takes place within the first four or five days of infant life. Certain bacteria also find their way into the upper portions of the tract, during the progress of labor, from the mother's vagina. The book presents a very concise description of this important subject.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting held at Philadelphia June 3, 4 and 5, 1904.

THE PRESIDENT, DR. C. B. G. DE NANCREDE OF ANN ARBOR IN THE CHAIR.

Address of the President.—Dr. C. B. G. DE NANCREDE of Ann Arbor, Mich., selected extirpation of the scapula as the subject of his address. He said that the statistics dealing with this operation were misleading, because cases in which the disease was primary in the scapula and secondary in the soft parts, those which were done in two stages, and those performed for benign growths, for caries, injury, and tuberculous disease, were all included in the statistics usually given. Indeed, in one paper, an operation in which the scapula was removed after death was included. There was no discrimination in any of the tables between operative recovery and the end results, investigation showing that a large number of subjects reported as having recovered had later died of recurrence of the trouble. The three-year rule had been ignored in like manner, for it was well known that this was utterly unreliable for any form of malignant disease. In one case there was an inoperable relapse at the end of five years, yet this was included by the reporter as a recovery. Careless examination of the patient and the expectation of finding marked difference between the physical signs in the two lungs often led to the opinion that pulmonary metastases had not occurred, the true explanation being that metastases were so numerous and so small and finely distributed that the physical examination was unreliable. The death rate probably was now lower with the new methods of operating, saving blood and preventing shock, and it was possible, therefore, that some of those who died in the past from shock and hemorrhage might have shown a few permanent cures if they had survived. It was a matter for future investigation to determine whether interscapulothoracic amputation would not give more permanent results. The usefulness of the upper extremity after the removal of the scapula was usually so marked that, of course, hesitation was felt about doing the operation just mentioned where the whole upper extremity was ablated. The details given in the tables seemed to warrant the above conclusions, which had proved to the author a surprise. There was only one case on record in which the details were obtainable sufficiently long to prove that it was really a cure, the patient being entirely well at the end of eight years. A few more were probably cured, although not under observation long enough to be past the time when a return of the growth might be noted. A vast number of those that were claimed as cured had been observed for from a few weeks to a few months only, and then lost sight of. Operations for pure enchondroma and other diseases demanding excision of the scapula presented very favorable results.

Chronic Intestinal Stasis.—Mr. W. ARBUTHNOT LANE of London, England, referred to his earlier communications on this subject, with special reference to the removal of the colon for chronic constipation, and described the technique of the operation. In nine cases he had removed the colon, and of this number one patient died from the bursting of a small abscess in the original cavity. In a number of private cases division of the ileum at its junction with the large bowel was effected, with no death from the operation *per se*. Removal of the large bowel was a serious operation; but the danger attending its performance varied with the degree of toxemia. He did not, however, recommend or advise such a radical operation until all other measures, medicinal and hygienic, had been tried. The danger of the operation could be reduced very materially by the subcutaneous injection of a large quantity of physiological salt solution immediately before operation.

Dr. J. C. BLOODGOOD of Baltimore said that chronic constipation had in some instances an anatomical basis. He would call attention to the use of the *x*-ray and injection of bismuth as a method of diagnosis in these cases. He believed this method would be used more frequently in the future in the class of cases under discussion, as it was used now in cases of aneurysms, bone lesions, etc. A day or two ago he operated on a patient who for three years had had pain in the lower abdomen. On exposing the right side some of the adhesions referred to by the essayist were found, and on exposing the left side the sigmoid could be lifted out of the abdomen as easily as one could lift out a loop of the small intestine. The anatomical lesion in this case was an enlarged sigmoid due to fecal matter. The sigmoid itself was normal. The mesentery was normal. These adhesions were separated with good results. In another case the adhesions were more pronounced. In this case the bowel was not resected, the patient being relieved by medical treatment. There was no difficulty in resecting the intestine and performing lateral anastomosis.

Dr. THOMAS W. HUNTINGTON of San Francisco said that it had seemed to him for many years that very many of these cases of enteroptosis, bearing especially on the large bowel, could be avoided by two things: (1) Careful attention in early life to the emptying of the bowel. It was a fact that in a large number of people in the hands of the average general practitioner a more or less permanent accumulation of fecal matter in the large bowel had been overlooked. (2) He believed this accumulation of fecal matter was due to a definite cause. Take, for instance, an appendix which had not given rise to the ordinary symptoms of appendicitis, but had caused sufficient irritation to interrupt the peristaltic wave and to bring about a condition of the bowel which was extremely disastrous in the carrying of residual material. Careful attention in early life to the emptying of the bowel would obviate the possibility of the occurrence of prolapse of the sigmoid, and by loosening up the large bowel and changing its environment or its relation we might avoid early operation for a pathological condition which existed. Careful study and search for the pathological condition, as an obscure appendix, would enable us to escape from the later consequences which the author had portrayed.

Dr. ARTHUR DEAN BEVAN of Chicago said that, as he understood the essayist, he made a plea for operative intervention in cases of chronic constipation. He would insist upon intestinal obstruction before he would undertake such an operation as the removal of a part or the whole of the colon for chronic constipation. The large and small bowels performed their functions admirably sometimes in spite of the presence of extensive adhesions. That was evident after many operations. They should discuss this as a sort of borderline subject in which in their cases they should call into consultation the internists. What would internists think of surgeons if they took the position of treating chronic constipation by resection of the large intestine or by anastomosis? Most of these cases could be very much better handled by internists by exercise, hygiene, etc., than by extensive surgical operation. Personally, he protested against advocating an operation so extensive as the removal of the colon for chronic constipation itself, and should insist upon reserving the operation for absolute intestinal obstruction.

Dr. JOHN F. BINNIE of Kansas City, Mo., understood Mr. Lane as advocating this operation for chronic intestinal stasis only after all other measures of treatment had failed. Personally he had practised cecostomy in a number of these cases with very fair temporary results, but had not observed them sufficiently long to determine whether or not the results were permanent.

Dr. JOHN B. ROBERTS of Philadelphia agreed partly with

what Dr. Bevan had said, because of some recent experience he had with intermittent obstruction of the bowel due to kinks and various other causes; but he realized that the essayist did not propose to open the abdomen of everybody for the relief of chronic constipation. After the internists had failed to afford relief to these patients by exercise, medical, and dietetic measures, surgical operations might do good. He was greatly pleased with the broad philosophical view which Mr. Lane had given of the whole question.

Dr. Maurice H. Richardson of Boston said that we must approach the surgery of the large intestine in cases of this kind, as Dr. Bevan had said, from the symptomatology of chronic intestinal obstruction. We all saw cases of complete chronic intestinal obstruction which demanded a most thorough radical operation. In one of his cases of complete volvulus of the sigmoid which threatened life, the sigmoid filled the whole abdomen, producing an acute obstruction of the bowel which necessitated immediate operation.

Dr. W. B. Coley of New York said that every severe case of acute intestinal obstruction required operation, and the operation was attended with great danger. Of nine cases operated on, death followed in all. He had reported to the New York Surgical Society a case of volvulus of the sigmoid, which was preceded by attacks of chronic intestinal obstruction, ending with an acute obstruction. He operated on the patient on the ninth day, when he was almost moribund, with great distention of the abdomen, high pulse, elevated temperature, etc. He opened the abdomen under cocaine anesthesia (as the patient could not stand a general anesthetic) over the sigmoid, relieved the obstruction, and the patient recovered.

Mr. Lane, in closing, wished to be distinctly understood that this form of operative treatment was suggested only after all other measures had failed.

The Fecal Origin of Some Forms of Post-Operative Tetanus.—Dr. Rudolph Matas of New Orleans, in a paper on this subject drew the following conclusions: (1) Notwithstanding the vast increase in our knowledge of the etiology, pathology, and prophylaxis of tetanus since the discovery of the drumstick bacillus of Nicolaier, a certain, not fully determined, number of post-operative deaths from this infection occurred in seemingly clean surgical cases which had not been satisfactorily accounted for. (2) While it had been fully and irrefutably demonstrated that the regional liability of the exposed parts of the body to tetanus (feet, hands, legs, forearms, arms, face, neck, etc.), was directly proportional to the degree of surface contact with tetanus-bearing (tetaniferous) matter (earth, manure, dust), the origin and regional distribution of accidental and post-operative tetanus in the concealed parts of the body (protected from surface exposure) had not been sufficiently investigated or recognized, surely not sufficiently insisted upon in accounting for post-operative deaths in which the rules of surgical asepsis had been apparently well observed. (3) Abundant experience had shown that while the risk of tetanus infection could be absolutely eliminated in all operations upon sterile tissues in which a rigorous postoperative asepsis could be maintained until healing had occurred, this liability could not be removed in those regions in which post-operative asepsis could not be secured. (4) In order of importance, next to the feet and hands and other exposed parts of the extremities, the injuries and surgical operations in those regions of the body which were most exposed to fecal contamination were the most liable to tetanic infection. In this category he would place the anorectal region, perineum, female genitourinary tract, male genitals, especially scrotum, lower pelvic region, including buttocks, sacrococcygeal region, groins, thigh, knee, upper leg, on their posterior surfaces especially; after operations on the intestines, artificial anus, etc., in all of which post-operative fecal contact was either constant or unavoidable, on account of proximity to the intestine. In considering this topographical distribution he excluded the direct but unconscious transmission of fecal matter to distant parts of the body by the soiled fingers of the patient himself or of his attendants. (5) The careful attention to the sterilization of instruments and the disinfection of the hands compelled by the rules of modern surgical, obstetrical, and veterinary practice had enormously reduced the liability to tetanic infection, even when those parts of the body were involved which were most exposed to fecal contact, by eliminating the direct inoculation of wounded surfaces with contaminated instruments and hands. However, the occasional post-operative deaths which occurred from time to time in the practice of competent and clean surgeons clearly pointed to another source of danger which was not dependent upon defects of technique or contaminated material, *e. g.*, imperfectly sterlized catgut, but to other sources of infection outside of and apart from the operative act itself which had not been adequately appreciated. (6) This hitherto unrecognized or disregarded factor in the causation of post-operative tetanus, at least in regions liable to fecal contact, was the direct contamination of the alimentary canal and its contents with living tetanus bacilli and their spores, swallowed in raw, uncooked vegetables, berries, and other fruits which were cultivated in fertilized or manured, *i. e.* tetanized soil. (7) It might be a mere coincidence, but it was a fact, that in all the cases of post-operative tetanus occurring after operations in regions liable to fecal contact which had been investigated by the author (two in his own practice), the patients had eaten copiously of uncooked vegetables immediately before the operation. The vegetable menu in these cases corresponded with the laboratory findings in regard to the vegetables found most frequently contaminated with tetanus germs and spores, viz., celery, lettuce, chicory, watercress, cabbage (cold slaw), radishes, turnips, carrots, tomatoes, and other green vegetables, strawberries, blackberries, and other berries and fruits which were grown in the soil or brought in contact with it, and which were largely consumed raw in an unavoidable contaminated state. (8) The tetanus bacillus and its spores were known to survive the passage through the intestinal canal of the domesticated animals, especially the herbivorous horse and cow, and the dung of these animals was a perpetual culture medium for the tetanus bacillus, swallowed constantly with the grass of the pasture and the fodder of the stable; not only were the bacilli ejected alive, but their virulence and activity were probably intensified by their temporary residence in the favorable conditions of the lower intestinal tract. This survival of the tetanus germ in a virulent state was fully demonstrated by the experiments of Sormani, Sanchez, Toledo, Veillon, Hoffman, and others, who demonstrated that the diluted excrement of the horse and cow, injected subcutaneously and otherwise, would kill rabbits in from five to six days with all the symptoms of this disease. These and other authors had fully demonstrated that the spores of the drumstick bacillus resisted the action of the digestive juices. It had also been demonstrated that the tetanus-laden feces of the healthy horse and cow were capable of producing fatal tetanus when brought in contact with wounded surfaces in these animals. (9) In view also of the fact that 5 per cent. of all normal men harbored the tetanus bacillus or its spores in an active state in the intestinal canal, and that the percentage of contaminated individuals was increased to 20 per cent. in hostlers, stablemen, dairymen, drivers, etc., the possibility of tetanus from fecal contact must always be kept in mind, especially when operating upon the anorectal region, perineum, and genitourinary organs of both sexes in unprepared subjects. (10) The author fully recognized that the normal defenses of

the organism against intestinal infection were, in healthy individuals, usually sufficient to protect it, even if the living tetanus bacillus had been freely introduced into the alimentary canal with the ingested food. It was only through the salutary and preservative influence of the protective mechanism, which largely neutralized the most virulent infections in the alimentary canal, that we could account for the great numbers who escaped when operations were performed in the recognized tetanogenic regions. It was evident, however, that even if tetanus infection was a comparatively rare post-operative sequence, it was well worth the observance of the simple precautions required to avoid this deadly accident. Precautionary measures would be more than justified if only one in ten thousand operative cases could be saved from the almost certain death which followed when this form of inoculation occurred after operation. (11) In accordance with the preceding statements, and his own convictions, the author had taught and insisted in his own practice, since his last and second post-operative death from tetanus occurred five years ago (perineoplasty and hemorrhoids), that no patient should be brought to operation without antitetanic preparation, whenever an operation was to be performed upon parts in which fecal contamination was unavoidable (hemorrhoids, fissure, fistula, stricture, etc.). (12) This antitetanic preparation was very simple and consisted of (*a*) purgation three days before the operation; (*b*) the suppression of all raw, uncooked food, especially green vegetables, berries, and other fruit for the same period of time before the operation. In emergencies, when dietetic preparation was impossible, 10 c.c. of tetanus antitoxin was injected subcutaneously at the time of the operation, while the patient was still under the anesthetic.

Dr. John E. Owens of Chicago wished to mention the case of a woman he saw a few years ago, past middle age, suffering from tetanus. She had no appearance of a wound, but two or three days before she consulted him she had a tooth pulled. Before the attack of tetanus began she had been eating celery, of which she was very fond, and he had no doubt the attack resulted from eating the uncooked celery.

Dr. Nathan Jacobson of Syracuse, N. Y., recalled one case in which tetanus developed after an operation for hemorrhoids, which was performed by a so-called rectal specialist, the so-called injection method having been resorted to. It was thought the tetanus was due to carbolic acid or to the ligature material that was used. In other cases of tetanus he had seen following operations on the anorectal region trismus was a late manifestation.

Dr. W. H. Hutchings of Detroit, Michigan, had treated three cases of post-operative tetanus: In one the tetanus followed an abortion; in another tetanus followed injuries to the hand; in a third tetanus followed an apparently clean operation for suprapubic shortening of the round ligaments; it developed twelve days after operation, but the wound healed by primary intention. All three patients recovered.

Dr. Joseph Ransohoff of Cincinnati, Ohio, a few years ago did considerable anorectal work, but never saw a case of post-operative tetanus, with one exception, and that was in the practice of a colleague. The patient had been curetted, and fuming nitric acid introduced into the uterus. Acute tetanus developed; but there was not trismus, but an open mouth, a symptom he had not seen before. In every case the alimentary tract should be thoroughly emptied.

Dr. Maurice H. Richardson of Boston had never seen a case of post-operative tetanus. It must be very rare when we considered infections through the alimentary canal, as acute appendicitis cases, enterostomies, and other operations by which the large intestine was opened.

Dr. Arthur Dean Bevan of Chicago asked if it was not possible that tetanus varied considerably in different localities.

Dr. Arpad G. Gerster of New York said that thirty-two years of surgical practice in two hospitals had failed to produce a single instance of post-operative tetanus to his knowledge.

Dr. Beverly Macmonagle of San Francisco, Cal., in an experience extending over thirty years, had seen but one case of tetanus following operation. In this case a trachelorrhaphy was done; catgut was used, and he had no doubt infection came from the catgut. He had operated in the houses of Italians and Spanish, who had horses, pigs, or cows adjoining their rooms, yet he had not had a case of infection from the tetanus bacillus in any of those bad surroundings.

Dr. Edmond Souchon of New Orleans remembered distinctly losing a young girl upon whom he operated for hemorrhoids. She died on the eighth day after the operation from tetanus.

Dr. F. H. Gerrish of Portland, Maine, some twenty-five years ago, had in close proximinity to one another two cases of post-operative tetanus. One patient was a child in the teens, and tetanus followed an operation for necrosis of the tibia; in the other tetanus developed after ligation of hemorrhoids. Tetanus seemed to come in waves. In the year in which these two cases occurred tetanus was quite prevalent. Three years ago they had in the hospital with which he was connected sixteen cases of tetanus in the course of eighteen months, and they were still in doubt as to the occasion for those cases.

Dr. J. Collins Warren of Boston thought it ought to be said in this discussion that tetanus was to a certain extent a tropical disease; that latitude had some influence upon the growth of the bacillus of tetanus, and that in the tropics it grew more luxuriantly than in temperate zones.

Dr. S. Stillman of San Francisco could see how there was danger of tetanus developing after ligature operations for hemorrhoids. That was the experience of Lane in the navy on the Pacific Coast, at Panama, and in the early days in San Francisco. The danger was a real one at that time, and as his experience was extensive in those days, it also happened in his own work a number of times; but no particular precautions were taken to guard against tetanus developing.

Dr. Albert Vander Veer of Albany, N. Y., said that his experience did not bring to his mind a single case of tetanus in connection with operations upon the rectum. The cases of tetanus seen in army practice generally resulted from shell wounds in which there was a great deal of dirt carried into the wounds; the wounds were badly lacerated, and they saw many cases of tetanus.

Dr. George E. Brewer of New York saw no objection to using serum as a prophylactic in these cases. They used it at the Roosevelt Hospital in all cases of injuries to the hands and feet. Seven years ago they had 16 cases of tetanus occur in about two months in the summer, following injuries of the hands and feet, and after that they made a definite rule in such cases to give them an immunizing dose of antitoxin, and since they had adopted that practice they had never had a case of tetanus develop there.

Dr. Dudley P. Allen of Cleveland, Ohio, said that they had a number of cases of tetanus at the Lakeside Hospital in Cleveland from the use of toy pistols. In every case where the wound was opened early and packed the patient recovered. The patient whose wounds were not opened early and packed died.

Dr. C. B. G. De Nancrede of Ann Arbor said that there were certain sections of the country where tetanus was unknown, while in others a few miles distant the disease was rife; at least, the germs of the disease could be found in the soil. For the past eleven years in his lectures he

had warned his students against the dangers of unripe fruit as possible source of tetanus.

Dr. Robert G. Le Conte of Philadelphia said that some fifteen years ago tetanus developed in a case that was operated on by a colleague in Philadelphia. The disease appeared on the eighth day following an operation on the perineum and resulted in death. At the Pennsylvania Hospital they formerly had a number of cases of tetanus, but since they had made it a rule to give patients with injuries of the hands and feet, or patients with suspicious-looking wounds, an immunizing dose of the antitetanic serum, they had not had tetanus develop.

Dr. Matas, in closing, said that at the Charity Hospital, New Orleans, there was no case of railroad injury that was contaminated with dirt that was not given antitoxin or antitetanic serum. In answer to Dr. Bevan, as we approached the tropics the prevalence of tetanus was increased. It was less prevalent in northern than in southern latitudes.

The Parathyroid Question.—Dr. Charles H. Mayo of Rochester, Minn., said that for more than fifty years reference had been made by various authors to peculiar gland bodies that were quite regularly associated or connected with the thyroid glands. As stated by careful observers, the glands were four in number, usually without the true capsule of the thyroid gland. They were six to seven mm. long, three to four mm. wide, and two and five-tenths mm. thick. The pathological changes were of simple type, *i.e.* degenerations, hemorrhages, cysts, and seldom tumors. In fact, there were but few tumors of the parathyroid reported, most of these being found at autopsy, and all were benign, mostly adenomata. From such reports, it would appear that these glands, as compared with other organs and lesions, were singularly free from serious diseases, especially those of a surgical nature. The association of function of the glands like the thyroid, parathyroid, thymus, suprarenal, and others became more marked as continued investigation disclosed the various changes consequent on disease or removal of the various glands. It was quite possible that the human being with four parathyroids had some to spare, and that if those on one side were preserved, no untoward consequences would follow. This phenomenon had been noted in other double structures—the kidneys, ovaries, etc. Operations upon cases of hyperthyroidism were usually confined to one side, and, the blood supply being free, there was but little danger of subsequent hypothyroidism, the greatest danger occurring from operations on both sides and from secondary operations on the remaining side in single goiter. Should tetany follow the removal of the parathyroids, the indications were to administer calcium salts to maintain life until parathyroid glands could be secured, transplanted and function obtained, as by this means it might be possible to tide the patient over into a chronic state which might later become a cure. In nearly 1,200 operations for goiter they had seen no tetany.

(*To be continued.*)

THE AMERICAN THERAPEUTIC SOCIETY.

Tenth Annual Meeting, Held at New Haven, Conn., May 6, 7, and 8, 1909.

F. H. Gerrish, M.D., of Portland, Me., President, in the Chair.

Thursday, May 6—First Day.

The proceedings of the opening session included an address of welcome by President Arthur Hadley of Yale University, with response by Dr. Thomas E. Satterthwaite of New York; a report on The Quality of Fluid-extract of Ergot at Present on the Market, by Horatio C. Wood, Jr., of Philadelphia, Secretary of the Standing Committee on Therapeutic Research, and an obituary of Dr. Robert Reyburn, a former President of the Society, prepared by Dr. Howard H. Barker and read by the Secretary, Dr. Noble P. Barnes of Washington, D. C.

President's Address: The Therapeutic Value of Hypnotic Suggestion.—Dr. F. H. Gerrish of Portland, Me., said that as psychotherapy had not previously been discussed at the meetings of the Society, as it was important that every practitioner should be well grounded in its principles and familiar with its practice, as its presentation was almost invariably a grotesque mixture of truth and error, and as most physicians and some neurologists knew little or nothing about it, the time seemed opportune for a serious, scientific study of the subject by the Society. Therefore, a symposium had been arranged, and eight experts engaged to present various aspects of psychotherapy, while he himself had taken Hypnotism as a Remedial Agent for the subject of the present address. When in general practice he had used hypnotic suggestion extensively, and he wanted the profession to do this method of treatment justice and appreciate its practical usefulness in daily medical work. Everybody was at all times more or less amenable to suggestion, and the hypnotic state was induced, not because it was curative, but because the condition was peculiarly favorable to the reception and retention of suggestions. Having described in detail a method of inducing hypnosis, the speaker said that this kind of treatment was especially valuable in so-called functional diseases of the nervous system, such as those characterized by pain, insomnia, abnormal nervous irritability, depression of spirits, phobias, obsessions, neurasthenia, moral obliquity, spasm, nausea, sexual perversions, and drug-habits; and an illustrative case was given under each of these heads. The principal erroneous opinions concerning hypnotism were then generally taken up and discussed; after which he said that hypnotism was often but little understood by men who affected to instruct the profession about it. None, however, had displayed incompetency in this regard quite so conspicuously as Dubois, whose work had been much commended by some physicians. This authority disparaged hypnosis, while admitting that he used it, and he showed conclusively that he had no understanding of the psychological principles of hypnotism. In conclusion, Dr. Gerrish said that the employment of psychotherapy is not incompatible with the use of physical agents of any description. The wise physician takes advantage of every available means, or combination of means, that will help his patient.

The Standardization of Materia Medica Products.—Dr. F. E. Stewart of Germantown, Pa., said that this subject embraced a much wider scope than was usually realized, and that many problems were involved, scientifically, professionally, and commercially. Having given a review of what had thus far been accomplished, he concluded by advocating the establishment of a strong central committee or bureau of materia medica, representative in character, which should have for its functions the co-operation, classification, and standardization of the newer materia medica, the censorship of advertising, the promotion of professional and commercial interest, and the protection of the public from dishonest commercial exploitation.

Dr. Wood said that he once thought Dr. Stewart's plan a very valuable one, but such a bureau was now unnecessary, on account of the national Food and Drugs Act and the similar laws passed by the different States. The thing which was required was some means of determining between good drugs and bad drugs, and this matter now depended on the authors of the U. S. Pharmacopœia and the enforcement of the law by the Government, which had made the Pharmacopœia the legal standard.

Dr. S. L. Dawes of Albany, N. Y., thought that a large number of useless drugs should be weeded out of the

Pharmacopœia. The first thing to be done was to find out by physiological experiment what drugs were really efficient, and then it would be a simple matter to standardize the few which were left.

Symposium on Diabetes.—Experience with Oatmeal Diet.—Dr. A. C. Crofton of Chicago said that the oatmeal treatment was the only notable advance in the therapeutics of diabetes within recent years. Its adoption had been purely empirical, but the clinical evidence now accumulated seemed to entitle it to a more important place in the treatment of certain types of the disease than had as yet been conceded. There were no bad effects if the diet was properly administered, with careful observation of certain important precautions. The most brilliant results had been noted in the case of children, particularly if the oatmeal cure was commenced as soon as possible after the discovery of the diabetes.

Drugs Useful in the Treatment of Diabetes.—Dr. D. Olin Leach of Washington, D. C., said that, while he believed, with many others, that there was no drug which has a curative effect, there were a few which act as palliatives, and in some selected cases control to a large degree the output of sugar, render the patient fairly comfortable, and prolong his life. Opium and its derivatives, notably codeine sulphate, hold first place in the opinion of many practitioners, while many consider alkalies as important as opium in the treatment. Sodium bicarbonate in large doses (8 to 10 drachms daily) should be given in cases showing diacettic acid or oxybutyric acid in the urine, and especially if diabetic coma was impending. Gold and arsenic bromide were highly thought of, and some noticeable results were reported from the use of this agent in combination with enzymes of the islands of Langerhans. The salicylates were extensively used, especially in the case of children. Grude recommended calcium for improving the general condition and as a prophylactic against boils and carbuncles, and Wilcox, uranium nitrate, especially in combination, with codeine, for retarding the transformation of glycogen into sugar. Other remedies worthy of mention were eugenia jambolina, potassium permanganate, potassium iodide, and emulsions of mixed fats. In cases believed to be due to ptomaine poisoning mercuric chloride had sometimes been used with good effect. Diet had been well designated the corner-stone of treatment in diabetes, and we could expect no beneficial results from drugs without careful and constant attention to this.

Surgical Features Relating to the Effect of Gallstones, and the Question of Operation in the Presence of Diabetes.—Dr. Robert T. Morris of New York said there were two special objections to operating upon the subjects of diabetes: (1) The phagocytes did not properly perform their protective function; (2) repair was not carried on well, because the reparative cells were disabled. The reason for this was on account of the cells being deprived of the water essential to their activity by the hygroscopic action of the sugar in the circulation. It had been observed that if gangrene appeared in a case in which diabetes had developed rapidly, the process was likely to go on. On the other hand, on a patient who had had diabetes for years, even if there had not been much reduction in the sugar, we could operate much more boldly. In cases of gallstone disease in which operation was indicated there came up the question of comparative danger. Was the greater danger to be apprehended from operation or from the continuance of the condition without surgical interference? In certain cases the formation of gallstones would appear to precipitate diabetes; and so of other sources of continued irritation. Glycosuria, like cough, was a symptom, not a disease, and in cases where there was no such evident cause as the changes accompanying arteriosclerosis a careful investigation should always be made, with a view to finding out the possible presence of some peripheral causative factor.

The Treatment of Diabetes as an Infectious Disease.—Dr. Arthur King of Portland, Me., said that the idea that diabetes might be an infectious disease was not new. Leo believed that it was due to a toxic agent, and had produced glycosuria in dogs by administering both fresh and fermented diabetic urine; while Sir Almroth Wright had thrown out the suggestion that there might quite well lie at the root of pancreatic diabetes a bacterial infection which might perhaps be amenable to vaccine therapy. About the middle of January last Dr. King became impressed with the idea that diabetes was a fungous disease, and an examination of the feces of a diabetic showed the presence of the yeast fungus, *Saccharomyces cerevisiæ*, in the alimentary canal. After the use of a solution of sodium citrate and sodium chloride, to prevent coagulation of the blood, he had been able to get a pure culture of this fungus from every case of diabetes which he examined. The next question to settle was, Did the fungus do its work in the alimentary canal or in the blood? This was easily answered, for one case on a liberal diet was taken with a profuse diarrhea, and the filtered discharge showed no glucose. The problem had now resolved itself into this: Could a yeast fungus, existing in such abundance that a culture could be obtained from less than a drop of blood and producing enzymes which would change glycogen and various sugars into glucose, be the cause of diabetes? In considering carefully all the pathological conditions met with in diabetes he could find nothing to oppose the theory that it was an infectious disease, while all other theories had encountered serious obstacles. During the last two months sixteen patients had been examined, and, as stated, a pure culture of the yeast fungus had been obtained in every instance. There had been no mixed culture. The solution alone on the culture media gave no growth. Cultures were quickly obtained on glucose agar, plain agar, or blood serum. The next question, What was the resisting power of the diabetic to this fungus? was answered by the use of Wright's method of taking the opsonic index. The examination of these sixteen cases showed three things: (1) The existence of innumerable yeast fungi in the blood of each one; (2) a disturbed power of resistance to this germ; (3) that the opsonic index registered a fair indication of the general physical condition of each. As to the value of vaccine treatment, he had been able to study its effect on but six patients, and that for less than two months, but the results were of considerable interest. Having given some details of these cases, the speaker went on to say that because diabetes was a disease of fermentation, because the yeast fungus was found in the blood, because its actions explained all the symptoms, as well as the pathological conditions, because the patients showed a disturbed power of resistance to this fungus, and because this lowered resistance was increased by treatment with vaccines, he believed that this yeast fungus was the cause of diabetes and that it should be treated as an infectious disease. The indications for treatment were to restore the lowered power of resistance, destroy or remove the cause, and prevent, relieve, or remove the complications which might arise. He was quite aware that he had not proceeded far in his investigation, but he trusted that he had gone far enough to make his paper worthy of the thoughtful consideration of the members of the Society.

Friday, May 7—Second Day.

The Therapeutics of Solution of Calcium Creosote.—Dr. L. Kolipinski of Washington, D. C., said that this preparation possessed all the medicinal virtues of creosote and none of its objectionable actions. Among the conditions in which he had found it valuable were pneumonia, pleuro-pneumonia, typhoid fever, cholelithiasis, scrofulous keratitis, nasal catarrh, tuberculous disease of the bones and joints, hemorrhoids, and the summer diarrhea of

infants. His colleague, Dr. A. J. Hall, had found it of service in appendicitis not demanding section. In pneumonia he claimed that calcium creosote cut short the disease, lowered the temperature, slowed the respiration and pulse, and apparently acted as a pulmonic antiseptic. Typhoid, he said, was very successfully treated with it. The average duration of all ages was fifteen days, and many cases yielded in seven to nine days. In tuberculosis of the viscera and of the mucous and serous membranes, and notably in pulmonary tuberculosis, he had not observed any beneficial effect on the progress of the disease or in the abatement of any of the severer symptoms; but in the pretuberculous state the remedy had proved very advantageous.

Time versus Pseudo-Opotherapy.—Dr. C. E. deM. Sajous of Philadelphia said that if ever our object to place pharmacology on a scientific basis was to be realized we should insist that whenever an agent was to be tried therapeutically there should be a preliminary determination of its identity as a chemical body. Thus only would it be possible for us to establish its physiological action on a sure footing. Just as opium contained various principles, the animal extracts contained a multiplicity of substances, cellular and plasmatic, and also products of cellular metabolism capable of provoking physiological effects; but here very little effort had been made to isolate the truly useful principles. Hence the confusion and empiricism which had always surrounded the use of these agents. It was unquestionably a fact that we had, among the twenty or more animal extracts which had been proposed, a few at least which were capable of affording relief in certain conditions where no other class of agents would act; and by "true" agents he meant those which could be used intelligently; that is, with knowledge of the physiological effects produced, because their active principles were known. Thyroid extract belonged to this class, since we knew that its action was due to the iodine its secretion contained in organic combination. Adrenal preparations likewise were included, because their active principles, whether epinephrin, suprarenalin, or adrenalin, were also known. Conversely, by "pseudo" agents he meant those animal extracts which were used blindly, without knowledge of their components, in almost any disease related directly or remotely to the organ from which the extract was obtained. The speaker took up the study of four extracts, the testicular, ovarian, renal, and pituitary, and stated that the peculiar advantages which were no doubt to be derived from the use of the various animal extracts would only become available when the empirical employment of them now prevailing would have been rendered impossible through proper identification of those of their constituents which brought about beneficial effects, the natural precursor to a clear conception of their mode of action.

Symposium on Diet.—Chronic Constipation Clinically Considered.—Dr. L. M. Gompertz of New Haven read this paper. From an experimental investigation he concluded that the common practice of civilized man to discharge the feces in the morning was based on the physiological experience that the food and digestive residues of the previous day's intake have had abundant opportunity to traverse the alimentary tract. After classifying the most frequent causes of constipation, he said that concerning diet as a cause, the unusual dryness of the stools had been explained by a too rapid absorption of the foodstuffs and water. Studies made in Prof. Mendel's laboratory had shown that whereas ordinary carbohydrates were very imperfectly utilized, a considerable number of unusual carbohydrates, such as occurred in many seaweeds, etc., were not attacked by the digestive enzymes. As a result of this investigation, agar agar was suggested as likely to prove of value in chronic constipation, and Dr. Gompertz, in order to test the matter clinically, had systematically given this substance to thirty patients, the majority of whom were unable to have an evacuation without the aid of medicine. The agar agar was taken morning and evening, beginning with 15-grain doses, and in most instances was eaten with milk or cream in the same way as an ordinary breakfast food. After regular movements of the bowels were secured the quantity was gradually reduced. The effect of the agar agar on the stool confirmed Mendel's theory, as in all cases there was a pronounced increase in the volume of feces passed, and, instead of the small, hard, dry, scyballous masses, the evacuations were well formed and of a dough-like consistency.

The Etiology and Pathology of Chronic Looseness of the Bowels.—Dr. A. D. Blackader of Montreal said that this condition might be dependent, primarily, upon (1) excessive propulsive peristaltic action, (2) an abnormal increase in the amount of secretion from the mucous membranes and secretory glands of the canal, and (3) defective absorption; and these might work in a vicious circle. Closely associated with these conditions was an abnormal development of bacteria in the alimentary tract. In considering the etiology clinically we noted first that loose evacuations might be occasioned by the mechanically irritating character of the food. The exact effect on peristalsis of intestinal indigestion due to insufficiency in the secretion of bile and pancreatic juice could not be stated positively. In conditions of impaired intestinal digestion the clinical investigator must always bear in mind that in some individuals the intrinsic nervous mechanism of the intestines was particularly susceptible to impulses received from the great central nerve centers. Diarrheas attributable to this excessive nervous irritability were not infrequently seen in Graves' disease, hysteria, and neurasthenia. Loose evacuations were occasionally due to a vicarious elimination of toxic products in the blood. The diarrhea of Bright's disease was well known, and a diarrhea of elimination might also occur in malaria, pneumonia, septicemia, and various infectious fevers. In gouty attacks any checking of the arthritic manifestations might induce a diarrhea. Lastly, we might have loose evacuations due to disturbances of the blood or lymph circulation, as in the congestion associated with a failing right ventricle or with a blocked thoracic duct.

The Relation of the Foodstuffs to Alimentary Functions.—Dr. Lafayette B. Mendel, Professor of Physiological Chemistry in Yale University, in place of the usual discussion of the effect of the digestive processes upon foods, considered the relations from a different and somewhat reversed viewpoint, namely, the influence of the foods upon various alimentary functions, and pointed out that such influences were worthy of consideration for their possible therapeutic significance. He reviewed the modern theory of hormones, or chemical excitants, and presented the facts bearing on the importance of such agents in exciting secretory functions and regulating glandular activities. Special attention was devoted to the formation of a gastric secretagogue, gastrin, by the action of certain food substances, like meat extracts, dextrin, etc., on the pyloric portions of the stomach. He pointed out that the clinician could provoke the flow of gastric juice by appropriate selection of foods, and repress it likewise (as by the use of fats) in dietetic as well as nervous ways. The sequence of effects which follow stimulation of secretory glands, along the digestive tube was reviewed, and the interrelation of such activities discussed. The speaker further considered the secondary consequences of variations in secretory activity which were induced by dietetic factors. Examples of such were found in the relation of the gastric sphincters to acid contents in the stomach, intestinal putrefaction, and other similar phenomena. He touched upon the possibility of regurgitation reactions as

well as other peristaltic actions which were related indirectly to the nature of the food intake, and considered the question of adaptation of glands and their secretions to specific diets with a rather unfavorable critique. He also discussed the relation of food intake to intestinal functions from the standpoint of both Metchnikoff and Finkelstein and their followers. In conclusion, Prof. Mendel made a plea for an earnest consideration of the possibilities of dietotherapy, in distinction from that type of feeding which was guided by chance or ruled by tradition.

The Present Knowledge of the Action of Cathartic Drugs.—Dr. F. P. Underhill, Assistant Professor of Physiological Chemistry in Yale University, in a paper on this subject, arrived at the following conclusions: It was apparent that cathartics might act upon the alimentary tract in a variety of ways, involving physical, chemical, and physiological activities. With the saline cathartics the essential factor was the production of an intestinal secretion by nerve stimulation, with a simultaneous inhibition of absorption. Peristalsis was secondary, and the consensus of evidence indicated that osmosis played but a subsidiary rôle, while mechanical irritation was absent. Most of the vegetable cathartics were peculiar in that they would produce their characteristic effects by whatever channel introduced, although their subcutaneous injection might be followed by untoward results. It was possible that the proposed derivatives of phenolphthalein would obviate this difficulty. Unlike the saline cathartics, presence in the blood appeared to be the essential factor of the action of vegetable purgatives. The principal effect of this class of agents was the production by local irritation of a very active peristalsis, which hurried the intestinal contents along the canal. From recent observations we had learned that different drugs might act upon entirely different portions of the alimentary tract. Thus the purgative oils, according to their condition (presence or absence of decomposition products) might influence the movements of the stomach and intestine or of the intestine alone, while a drug like senna showed no action until the large intestine was reached. Peristalsis and purgation were not synonymous terms. Peristalsis might be of two distinct types, either pendular movements without progression of the intestinal contents or peristalsis by which the contents were passed along; and it was the latter type which was effective in purgation. In complications where it was very desirable to induce hypersecretion along the alimentary canal the salines should be avoided. On the other hand, they were indicated in conditions of sluggish secretory activities. Since secretory activity necessitated increased blood supply to the parts involved, the drawing of blood from other portions of the body might or might not be desirable. The increased secretion poured into the alimentary canal accounted for the efficacy of the salines in removing fluid from the body in edematous conditions. The employment of vegetable cathartics was contraindicated in conditions where the canal was already in a state or irritation, for these bodies were primarily irritants. They were indicated where the intestinal movements were sluggish, and certain of them might be given when specific portions of the tract needed stimulation.

(To be continued.)

Skin Grafting with Frog Skin.—J. H. McVay of Toledo, Ohio, reports the case of a child severely burned, on whom he used frog skin instead of human skin for the purpose of grafting. The frog was immersed in 1 to 500 bichloride solution and then in saline. Held in sterile gauze by the nurse, strips of skin were taken from the belly and applied to the child. The dressing was first rubber tissue, then gauze moistened with warm saline solution, cotton, and bandages. The grafts "took" well.—*Cleveland Medical and Surgical Reporter.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

University of the State of New York.

February 2, 3, 4, and 5, 1909.

ANATOMY.

Answer any ten of the questions on this paper but no more.

1. Give the gross structure and the physical properties of bone.
2. Describe the clavicle and give its articulations.
3. Mention the muscles attached to the patella. Describe the origin and the action of *one* of the muscles mentioned.
4. Describe the pulmonary artery.
5. Give the boundaries and the contents of the popliteal space.
6. Give the origins and the terminations of the lymphatic vessels.
7. Describe the lacrimal apparatus.
8. Describe the pancreas and give its location.
9. Give the gross anatomy of the spinal cord (medulla spinalis).
10. Describe normal lung tissue.
11. Give the structure, blood supply and nerve supply of the uterus.
12. Mention the important ductless glands and describe *one* of them.
13. Give the structure of the urinary bladder. What is the distance between the orifices of the ureters in the bladder of the adult?
14. What are the coverings of a femoral hernia from without inward?
15. Outline fetal development at the beginning of the fourth month.

PHYSIOLOGY.

Answer any ten of the questions on this paper but no more.

1. In what marked particular does living matter differ from lifeless matter? What is metabolism?
2. State (*a*) the amount of blood in the adult human body, (*b*) the average temperature of the blood. Where in the body is the temperature of the blood highest? Why?
3. Describe the valves in veins and state their function. In what veins are valves absent?
4. Explain in detail the mechanism of normal inspiration.
5. What physiologic processes are involved in the manifestation of a fever?
6. Describe in detail an intestinal villus. What are the functions of the intestinal villi?
7. What substances are absorbed in the stomach? What effect has alcohol on stomach absorption?
8. What important functions of the body are dependent on the presence of NaCl in the body? Describe the preparation of normal salt solution.
9. Describe the function of the urinary bladder and of the sphincter vesicæ.
10. State the function of *each* of the following parts of the spinal cord: (*a*) white substance, (*b*) gray substance, (*c*) anterior cornua, (*d*) posterior cornua.
11. Describe the course of a motor impulse from its source in the cerebral cortex to the calf of the leg.
12. Describe the physiological function of the organ of Corti.
13. In what structures is the sense of taste located? Give the nervous mechanism of the sense of taste.
14. Describe the physiologic phenomena of lactation.
15. Explain the physiologic mechanism involved in a chill.

CHEMISTRY

Answer any ten of the questions on this paper but no more.

1. Define (*a*) chemistry, (*b*) atom, (*c*) compound, (*d*) mixture, (*e*) ion.
2. Define and illustrate (*a*) diads, (*b*) tetrads, (*c*) pentads.
3. Explain the uses of the spectroscope in chemical analysis.
4. Give the occurrence in nature, the preparation and the properties of (*a*) oxygen, (*b*) nitrogen.
5. How is boric acid prepared from borax? State the properties of boric acid.
6. State the uses of phosphorus. Give the treatment of phosphorus poisoning.
7. What is the principal source of iodine? Give the preparation of KI.

8. Give a chemical equation showing the preparation of ferrous chloride.
9. State the usual source and give the properties of (*a*) tannic acid, (*b*) tartaric acid.
10. Give the details of procedure in examining the stomach in a case of death from suspected poisoning by arsenic.
11. Give in detail a test for (*a*) indican in the urine, (*b*) albumin in the urine.
12. Define (*a*) alcohol, (*b*) aldehyd, (*c*) carbohydrate.
13. Describe human milk as to (*a*) composition, (*b*) reaction, (*c*) specific gravity.
14. State the source and give the chemical composition of any *one* of the following: (*a*) pepsin, (*b*) ptyalin, (*c*) bilirubin.
15. Give the names and the formulas of *three* substances used for disinfecting purposes. Explain the chemical action that makes any *one* of these substances valuable as a disinfectant.

HYGIENE AND SANITATION.

Answer any ten of the questions on this paper but no more.

1. What sanitary regulations should be enforced by health boards to prevent milk infection?
2. How long does a diphtheritis patient remain infective? How may it be shown that the infective period of diphtheritis has passed?
3. What are the most reliable sources of a pure water supply? Mention the objections to the use of river water for drinking purposes.
4. Is heredity a factor in disease? Illustrate.
5. Discuss the relative merits of disposing of the dead by burial and incineration.
6. Give the management of a case of heat prostration.
7. What diseases ordinarily render the subject immune from subsequent attacks of the same diseases?
8. Define and illustrate a nuisance under a public health act.
9. How may soil become polluted? What method may be adopted to neutralize the evils likely to result from polluted soil?
10. What is the normal proportion of CO_2 in air? What proportion of CO_2 in air is dangerous to health?
11. Mention the requisites for an indoor sanitary water closet.
12. Mention the infectious varieties of mosquitos. Describe the manner in which malarial infection is conveyed by the mosquito.
13. Give reasons for concluding that breast-feeding for infants is more hygienic than artificial feeding.
14. State methods of disinfection by (*a*) heat, (*b*) liquid chemicals, (*c*) gases. Illustrate in each case.
15. Describe a method of intermittent filtration of sewage.

SURGERY.

Answer any ten of the questions on this paper but no more.

1. Describe *two* methods of producing local anesthesia and state to what conditions each method is adapted.
2. With what disease is gangrene frequently associated? Describe the treatment of moist gangrene of the foot.
3. Give the symptoms and the surgical treatment of abscess of the liver.
4. Describe the treatment of (*a*) a bullet wound of the leg, (*b*) a wound of the hand made by a toy pistol.
5. What is a dermoid cyst? Give the symptoms and the treatment of a subcutaneous dermoid cyst.
6. Describe an approved method of disarticulation at the shoulder joint.
7. Give the symptoms and the treatment of acute osteomyelitis.
8. Define empyema of the pleura and describe an operation for its relief.
9. Describe the treatment of a penetrating wound of the abdomen with injury to the viscera.
10. Define (*a*) thrombosis, (*b*) embolism. Describe the symptoms of venous thrombosis of the leg.
11. Describe morbus coxarius as to (*a*) early symptoms, (*b*) later symptoms.
12. Describe the treatment of a stricture of small caliber in the deep urethra.
13. What symptoms indicate the need of operation on the mastoid bone?
14. Give the symptoms of adenoid growths of the nasopharynx and describe an operation for their removal.
15. What is lupus? What measures should be adopted in its surgical treatment?

OBSTETRICS AND GYNECOLOGY.

Answer any ten of the questions on this paper but no more.

1. What conditions of the internal organs of generation are liable to cause abortion? State the reasons for such liability.
2. Define ectopic pregnancy. Mention the varieties of ectopic pregnancy and state the management of each variety.
3. State the essential causes of pernicious vomiting of pregnancy. What should be the management of such a condition?
4. What principal causes operate to delay labor in the first stage? What should be done to overcome the difficulties causing the delay?
5. Mention the indications for the induction of premature labor at the eighth month. Describe the most available effective operation.
6. Mention the varieties of placenta prævia and give the management of each variety.
7. Give the management of the perineum during pressure of the head and delivery.
8. Relate in detail prophylaxis of ophthalmia neonatorum.
9. Define puerperal phlebitis and give its etiology and its treatment.
10. Give the diagnostic indications of retrodeviation of the uterus complicating pregnancy and outline a corrective procedure.
11. Differentiate vaginitis and vaginismus. Give the management of each condition.
12. What are the dangers to the female from latent gonorrhea? How should the resultant infection be treated?
13. How may uterine carcinoma affect gestation and delivery? Illustrate.
14. What are the causes and the results of atresia of the vagina? How should the resultant conditions be managed?
15. Differentiate menorrhagia and metrorrhagia. Give the management of each condition.

PATHOLOGY.

Answer six questions, but no more.

1. Describe the vesicle of variola. What are the secondary lesions of variola?
2. What are the lesions of infantile scurvy (scorbutus)?
3. Describe the macroscopic and the microscopic appearances of syphilitic gummata.
4. Enumerate the histoid (simple) tumors and state the tissue of which each is composed.
5. Define (*a*) plethora, (*b*) active hyperemia, (*c*) passive hyperemia, (*d*) edema, (*e*) anemia.
6. What are the usual evidences of death from abortion as revealed by an autopsy?
7. Describe (*a*) retention cysts, (*b*) exudation cysts.
8. Describe the lesions of the kidney cortex in acute diffuse nephritis.
9. Describe the microscopic appearances of the tissues affected in tuberculous pleuritis.

BACTERIOLOGY.

Answer four questions, but no more.

1. Describe the microgametes or flagella of the plasmodium malariæ.
2. State briefly a method of obtaining a pure culture.
3. Define coccus. Give an example of a pathogenic coccus.
4. Describe the process by which bacteria multiply.
5. State cultural characteristics that differentiate the colon bacillus and the typhoid bacillus.
6. What is the supposed microorganism of cerebrospinal meningitis? How is the bacteriological diagnosis of this disease made?

DIAGNOSIS.

Answer any ten of the questions on this paper but no more.

1. Differentiate lung hepatization and pleuritis with effusion.
2. Describe the condition known as catalepsy.
3. Mention the varieties of casts found in the urine and state the diagnostic significance of each.
4. State the distinctive characteristics of mastoiditis requiring an operation.
5. How does eczema differ from herpes zoster?
6. State the significance of hemorrhage by diapedesis.
7. Describe puerile respiration and state its causes.
8. What changes take place in the heart in mitral regurgitation?
9. What is the clinical significance of (*a*) an excess of sodium chloride in the urine, (*b*) a diminution of sodium chloride in the urine?
10. State the value of the ordinary leucocyte count in differential diagnosis.
11. State the course of the temperature in (*a*) incipient tuberculosis, (*b*) typhoid fever, (*c*) tonsillitis.

12. What are the plantar reflexes? What is the diagnostic value of the plantar reflexes?

13. Give the character of the cough and of the expectoration in acute catarrahal bronchitis.

14. What are the symptoms caused by a biliary calculus from its first manifestations till its voidance *per vias naturales?*

15. State the diagnostic value of a macroscopic examination of the vomitus. Illustrate.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

February 2, 3, 4, and 5, 1909.

ANATOMY.

5. THE POPLITEAL SPACE is *bounded*: *Above, and externally* by the Biceps; *above, and internally* by the Semimembranosus and Semitendinosus; *below, and externally* by the Plantaris and external head of the Gastrocnemius; *below, and internally* by the inner head of the Gastrocnemius.

Contents: Popliteal vessels with branches, external saphenous vein, external and internal popliteal nerves, small sciatic nerve, lymphatic glands, and loose areolar tissue.

6. The *lymphatic vessels originate* in: (1) The lymph spaces, interstices between the cells and fibers of almost all tissues; (2) within the villi; (3) in the so called perivascular spaces; (4) in the stomata in the walls of various serous cavities, the peritoneum, pleura, and pericardium. They terminate in the thoracic duct and right lymphatic duct, which enter the venous system at the junction of the internal jugular and subclavian veins on the left and right sides of the neck respectively.

11. UTERUS. *Blood Supply*: The uterine and ovarian arteries and veins.

Nerve Supply: The third and fourth sacral nerves, and the inferior hypogastric and uterine plexuses.

12. The important *ductless glands,* are: Spleen, thyroid, thymus, suprarenals, parathyroids.

The *spleen* is situated in the back part of the left hypochondriac and epigastric regions, being covered by the ninth, tenth, and eleventh ribs, on the left side. It is of an oblong, flattened form, the external surface being convex; on the inner surface is a vertical ridge dividing it into two parts, the posterior of which is applied to the outer surface of the left kidney, while the anterior one receives the tail of the pancreas, and lies against the cardiac end of the stomach. Near this ridge is a fissure, *the hilum,* where the vessels enter. The anterior border is notched, and the lower end is pointed and rests on the costocolic ligament, situated in the left hypochondriac region. It is covered by peritoneum, except at the hilum, where it passes forward and inward in a double line enclosing the vessels, as the gastrosplenic omentum, to the fundus of the stomach. It usually measures 5 by 3 by 1 or 1½ inches, and weighs about 7 ounces.—(From *Aids to Anatomy.*)

13. The distance between the orifices of the ureters in the bladder is a little less than two inches.

14. The *coverings of a femoral hernia,* from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous areolar tissue, and peritoneum.

PHYSIOLOGY.

1. Living matter differs from lifeless matter in possessing the capacity for nutrition, reproduction, sensibility, motion, and evolution. In a word, living matter is capable of metabolism; lifeless matter is incapable of metabolism.

Metabolism is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (anabolism), and (2) destructive (katabolism).

2. (*a*) The amount of blood in the adult human body is about one-thirteenth of the body-weight.

(*b*) The average temperature of the blood is about 100° F. The temperature of the blood is highest in the hepatic vein; this is due to the oxidation and metabolism occurring in the liver.

3. The valves in veins are a reduplication of the internal coat with some connective tissue and elastic tissue to give them strength. They are much like the semilunar valves of the heart, but their free margins are turned towards the heart. They are generally arranged in pairs. They allow the blood to pass towards the heart, but prevent it passing in the opposite direction; they thus aid in the venous circulation.

Valves are absent from the following veins: The venæ cavæ, hepatic veins, portal vein and its branches, renal, uterine, ovarian, pulmonary, cerebral, spinal, and umbilical veins. The sinuses of the skull and very small veins are also without valves. These veins, not being liable to pressure, do not require the action of the valves, the chief function of which is to prevent a reflux of blood back towards the capillaries.

7. Substances that may be *absorbed* in the *stomach* are: Water, alcohol, salts, sugars, and dextrins that may have been converted from starch by the ptyalin of the saliva, and proteoses and peptones resulting from peptic digestion of proteids.

Alcohol "promotes the absorption of accompanying substances (sugar, peptone, potassium iodid), and stimulates the flow of the gastric juice. In this matter it acts as do other condiments (salt, pepper, mustard, peppermint), but if there be too great an irritation of the mucous membrane there is less activity (dyspepsia). The rapid absorption gives to alcohol its quick recuperative effect after collapse, and its value in administering drugs, especially antidotes. Alcoholic beverages combining alcohol and flavor promote gastric digestion and absorption, but often stimulate the appetite in excess of normal requirements. Alcohol is burned in the body, but may also be found in the breath, perspiration, urine, and milk."—(*American Text-Book of Physiology.*)

8. Sodium chloride aids in the processes of endosmosis, and so of absorption, and hence of metabolism in general. It aids in the splitting up of the proteids: it holds in solution the globulins; it also, by means of chemical decomposition, provides the chlorine which goes to form the hydrochloric acid of the gastric juice and the potassium chloride of the blood corpuscles and the muscles.

Normal salt solution is prepared by dissolving six grams of sodium chloride in one liter of sterile water.

10. In the spinal cord: (*a*) The white substance simply conducts nerve impulses: (*b*) the gray substance contains groups of cells which act as centers for and distributors of nerve impulses, and are also concerned in reflexes; (*c*) the anterior cornua have a motor and trophic function; (*d*) the posterior cornua are sensory.

11. The motor impulse would start in the cerebral cortex (upper part of the precentral convolution), pass through the corona radiata, internal capsule, crus, pons, medulla, crossed and direct pyramidal columns, to the motor cells in the anterior cornu of the spinal cord; thence down the spinal cord to the lumbosacral cord, through sciatic nerve, to internal popliteal nerve (which supplies muscles of the calf of the leg).

12. The organ of Corti is the receptive apparatus for hearing; it analyses sounds, and translates the vibrations of physical sounds into physiological nerve stimuli. But *how* this is accomplished is not known.

13. The sense of taste is chiefly located in the tongue (papillæ or dorsum, posterior part, edges, and tip); also in hard and soft palate, tonsils, fauces, uvula, epiglottis, and pharynx. The taste buds and cells are terminations of the gustatory nerves.

The nerves concerned in taste are: (1) The glossopharyngeal, which is distributed to the posterior third of the tongue, is said to be concerned with the sensation of bitterness; (2) the lingual branch of the trigeminus, which is distributed to the anterior two-thirds of the tongue, and is said to be concerned with sweet and acid tastes. The chorda tympani is also believed to be involved with the sense of taste in this part of the tongue.

The center for taste is supposed to be in the uncinate gyrus.

CHEMISTRY.

1. (*a*) *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes.

(*b*) An *Atom* is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule.

(*c*) A *Compound* is a substance made up of two or more elements, chemically united, in definite proportions.

(*d*) A *Mixture* is the product obtained by uniting into a more or less homogeneous whole, two or more substances whether elements or compounds, in any proportions, and without chemical union.

(*e*) An *Ion* is the primary product of electrolysis.

2. (*a*) *Dyads* are elements (or radicals) which have a valence of two; as oxygen, sulphur. CaO; H_2S.

(*b*) *Tetrads* are elements (or radicals) which have a valence of four; as, carbon, silicon. CH_4; SiO_2.

(*c*) *Pentads* are elements (or radicals) which have a valence of five; as nitrogen, phosphorus. NH_4Cl; PCl_5.

4. (*a*) Oxygen. *Occurrence in nature:* Free in the air and in combination in water, rocks, minerals, etc. It is more abundant than any other element, forming about 40 per cent. of the total weight of the earth.

Preparation: Oxygen may be prepared by heating a mixture of equal parts of potassium chlorate and manganese dioxide. The latter remains unchanged, while the former gives up all of its oxygen, according to equation:

$$2KClO_3 = 2KCl + 3O_2.$$

Properties: Oxygen is a colorless, odorless, tasteless gas, slightly soluble in water, heavier than air. It has a strong tendency to combine with other elements, and forms binary compounds with all elements except fluorine and bromine. Oxygen is necessary to the processes of life and combustion.

(*b*) Nitrogen. *Occurrence in nature:* Free in the air, in combination in nitrates, ammonia, and in many organic substances.

Properties: A colorless, odorless, tasteless gas, it neither burns nor supports combustion nor respiration, it has no tendency to unite with other elements.

Preparation: Nitrogen may be prepared by heating ammonium nitrite:

$$(NH_4)NO_2 = 2H_2O + N_2.$$

5. Boric acid is prepared from borax by slowly decomposing a boiling concentrated solution of borax with an excess of sulphuric acid, and allowing the acid to crystallize:

$$Na_2B_4O_7 + H_2SO_4 + 5H_2O = Na_2SO_4 + 4H_3BO_3.$$

Properties of boric acid: White, glistening plates, unctuous to the touch; odorless; having a slightly bitter taste, and without corrosive or poisonous action; soluble in water. It is a valuable antiseptic. When heated to 176° F. it loses H_2O and forms metaboric acid, HBO_2; and at 212° F. it forms tetraboric or pyroboric acid, $H_2B_4O_7$, whose sodium salt is borax.

6. The *chief uses of phosphorus* are in making matches, rat paste, and phosphor bronze. It is also used in medicine in cases of osteomalacia, rickets, and as a nerve tonic.

6. In *poisoning by phosphorus,* give an emetic such as copper sulphate or apomorphine hydrochloride; then old French oil of turpentine should be administered; avoid giving oils and fats; a weak solution of potassium permanganate has also been recommended.

7. The *principal source of iodine* is the ashes of seaweed, known as kelp.

KI is prepared by saturating a solution of potassium hydroxide with iodine, then evaporating, and calcining the resulting mixture of iodide and iodate with charcoal:

$$6KHO + 3I_2 = KIO_3 + 3H_2O + 5KI$$

8. Preparation of ferrous chloride:

$$Fe + 2HCl = H_2 + FeCl_2$$

9. (*a*) Tannic acid. *Usual source:* Nutgalls.

Properties: A light, amorphous, astringent powder, soluble in water, forms a precipitate with ferric salts and also with albumin and the alkaloids.

(*b*) Tartaric acid. *Usual source:* The juice of the grape; also fruits and vegetables (where it usually occurs as the potassium or calcium salt).

Properties: Colorless crystals, soluble in water and alcohol, acid taste, odorless.

11. *To examine for indicanuria:* "The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess."

To examine for albumin in the urine: "The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

12. (*a*) An *alcohol* is the hydroxide of a hydrocarbon radical, and capable of reacting with an acid to produce an ester and water.

(*b*) An *aldehyde* is the first oxidation product of a primary alcohol.

(*c*) *Carbohydrates* are compounds of C, H, and O, the two latter being generally in the proportion to form water; until recently they were of unknown constitution. This, while avowedly inaccurate, was generally accepted as a definition. A more modern definition is: "All aldoses and ketoses of the polyhydric alcohols which contain a HO group attached to the C atoms neighboring the aldehyde or ketone groups, as well as their anhydride-like condensation products."

13. Human milk. (*a*) *Composition:* Water, about 88+ per cent.; solids, about 11+ per cent. The latter are: proteins, about 1 to 2 per cent.; fats, about 3 to 4 per cent.; sugar, about 6 to 7 per cent.; and inorganic salts, a trace.

(*b*) *Reaction,* alkaline.

(*c*) *Specific gravity,* about 1029 to 1033.

14.

	SOURCE.	CHEMICAL COMPOSITION.
(*a*) Pepsin.....	Gastric juice.	Not known.
(*b*) Ptyalin.....	Saliva.	Not known.
(*c*) Bilirubin.....	Bile and biliary calculi.	$C_{32}H_{36}N_4O_6$.

15. (1) Hydrogen dioxide; H_2O_2. (2) Mercuric chloride; $HgCl_2$. (3) Potassium permanganate; $K_2Mn_2O_8$. Potassium permanganate acts as a disinfectant by oxidizing the organic matter with which it comes in contact.

HYGIENE AND SANITATION.

2. A diphtheritis patient remains infective while any membrane, discharge, or albumin in the urine remains, and while any bacilli can be found on bacteriological examination; generally about four weeks. The infective period may be believed to have passed when the patient is free from all signs of congestion or rhinitis, and when continued bacteriological examination is persistently negative.

3. The most reliable sources of a pure water supply are: Deep well water; rain water (theoretically); and water from large fresh-water lakes, provided it is taken from a point sufficiently distant from the shore to escape all danger of contamination from sewage.

The objections to the use of river water for drinking purposes are: The danger of its being polluted by sewage and refuse from houses, land, and factories. It is also liable to be impregnated with the minerals to be found in the soil over which it flows.

5. There is nothing to be said in favor of burial over cremation; it is sentiment rather than science or logic which prevents the entire abolition of burial.

The advantages of cremation over earth burial are: (1) Economy; cremation is very much cheaper, and there is no need for the community to purchase large tracts of valuable land for the accommodation of the dead. (2) Health; it is said that earth-burial causes the air to become poisoned, the burial grounds to become offensive, the soil to become laden with disease germs of every description, water to become poisoned, and diseases to be directly originated or propagated. (3) Body-snatching and desecration of tombs will be impossible.

7. As a rule one attack of the following diseases conveys immunity: Whooping cough, rötheln, scarlet fever, typhoid, typhus, smallpox, varioloid, chickenpox, yellow fever, mumps.

8. A *nuisance* is anything that injuriously affects the health or comfort of any members of a community. *Examples:* Carpet beating, tanning, square-wheeled cars.

10. The normal proportion of CO_2 in air is about four parts in 10,000. The exact proportion of it which is dangerous to health depends partly upon the amount of oxygen that is also present. From 1.5 to 2 per cent. of CO_2 produces headache, giddiness, and faintness; from 5 to 10 per cent. is fatal.

12. *The infectious varieties of mosquitos* are: (1) *Anapheles,* which conveys malaria; (2) *Stegomyia fasciata,* which conveys yellow fever; (3) *Culex,* which conveys filaria.

Manner in which the malarial infection is conveyed by the mosquito: "During the course of all the malarias there are formed in the blood oval spherical or crescentic bodies, some of which are flagellated, others non-flagellated. These are sexual elements of the parasites, the flagellated forms constituting the males, the non-flagellated, the females. Union of these in the blood, however, for some unknown reason, does not take place, but in the stomach of different species of mosquitos of the genus anopheles, which suck up the malarial parasites when biting. In the mosquito's stomach, coalescence (copulation) of the sexual elements occurs and a new organism is formed. The new parasite in turn forms other organisms in large numbers, which pass

from the mosquito's stomach to its body cavity and thence collect in its salivary glands; from this situation they find their way into the blood of man again when the insect bites. The forms thus inoculated give rise to malaria."—(From Langfeld's *Infectious and Parasitic Diseases.*)

SURGERY.

1. Local anesthesia can be caused: (1) By applying a mixture of salt and ice, or by spraying the part with ether or with ethyl chloride. (2) Cocaine hydrochloride, in watery solution of about 5 to 8 per cent., can also be applied to a mucous surface, or in a one per cent. solution it can be dropped into the eye. The same drug can be used hypodermically in solution of from 1 to 4 per cent., but it does not act on inflamed tissues. When injected into a finger or toe its action can be increased by the application of a tourniquet, which prevents the solution from being carried away in the blood current.

The freezing is adapted only to superficial operations, as opening an abscess. Cocaine can be used for amputation of fingers and toes, circumcision, etc.

7. Osteomyelitis. *Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

Treatment consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

11. Morbus coxarius. *Symptoms of first stage:* Night cries; lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

Symptoms of second stage: Abduction, limping, pain, which is worse at night, apparent lengthening of the limb, abscess, atrophy of thigh muscles, flexion of thigh, effusion into hip joint, and there may be crepitation in the joint.

Symptoms of third stage: Flexion, adduction, and shortening of the limb, the joint may be dislocated or ankylosed, or suppuration may occur.

15. *Lupus vulgaris* is a tuberculous infection of the skin; it is generally found upon the face, particularly the nose and cheeks. It begins as a pinkish nodule which is painless, and spreads to other nodules and generally ends in ulceration with destruction of mucous membrane or cartilage.

Treatment: In the early stages the small nodule may be excised. If not seen till later curettage with a sharp spoon, followed by cauterization with pure carbolic acid, has been recommended. This can be repeated at intervals of three or four weeks if necessary. Finsen light and tuberculin have also been used.

OBSTETRICS AND GYNECOLOGY.

8. *Prophylaxis of ophthalmia neonatorum:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth.

11. *Vaginitis* is a condition of inflammation of the vagina. It is characterized by redness, swelling, pain, heat, irritation, and increased secretion. There may be frequent and painful urination. *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated.

Vaginismus is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, caruncle myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

15. *Menorrhagia* is an excessive loss of blood at the menstrual periods.

Metrorrhagia is a hemorrhage from the uterus at other than the menstrual periods.

It is very often impossible to differentiate the two conditions.

Treatment: Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium; rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used.

PATHOLOGY.

3. *Syphilitic gummata* are firm, elastic, yellow or whitish nodular masses, varying in size from a tubercle to an orange. Their shape and outline are irregular, owing to fibrous processes which go through them; they often have a kind of capsule consisting of fibrous-looking but translucent material, which fastens them firmly to adjacent structures. On section they are mucoid or gelatinous, and vascular. *Microscopically,* they consist of round cells and giant cells, nuclei, fat granules and cholesterin; around this portion will be found epithelioid cells, and an outer layer consisting of leucocytes, giant cells, and epithelioid cells. There is some intercellar material; and blood-vessels are present.

5. (*a*) *Plethora* is the name given to the condition in which the total quantity of blood is (or was) supposed to be excessive.

(*b*) *Active hyperemia* means excess of arterial blood in a part, with, as a rule, acceleration of flow.

(*c*) *Passive hyperemia* means excess of venous blood in a part, with retardation of flow.

(*d*) *Edema* is the name given to the condition in which the liquid within the tissues is increased in quantity.

(*e*) *Anemia* denotes a condition in which there is a reduction of the quantity or quality of the blood (generally used with reference to the red corpuscles).

7. (*a*) *Retention cysts* are cysts which result from the retention of normal secretions; such as a sebaceous cyst.

(*b*) *Exudation cysts* are cysts which occur in cavities which have no excretory duct, and which are due to excessive secretion; such as a hydrocele.

BACTERIOLOGY.

2. *To make a pure culture:* "All that is necessary is to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth."—(*Reference Handbook of the Medical Sciences.*)

3. *Cocci* are spherical bacteria. The gonococcus (a diplococcus) is a pathogenic coccus.

4. Bacteria multiply by fission. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium just falls in two. It has been calculated that a single bacterium could, by fission, produce two in one hour. Fortunately, they seldom obtain food enough to keep up this process for any length of time.

5. *Cultural characteristics that differentiate the colon bacillus and the typhoid bacillus:* (1) On gelatin plates, the colonies of typhoid develop more slowly than those of colon bacillus.

(2) The colon bacillus causes fermentation with production of gas in media which contain sugar; the typhoid bacillus does not.

(3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.

(4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not.

(5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not

DIAGNOSIS.

3. "*Casts* in the urine occur in nephritis, and different varieties are found in the different forms of that disease. *Hyalin* casts occur in all forms of nephritis, in congestion of the kidneys, in jaundice, and even in health. *Waxy* casts occur especially in chronic parenchymatous nephritis. *Epithelial* casts occur especially in acute parenchymatous nephritis. *Granular* casts are especially common in chronic nephritis, but they may occur in acute nephritis. *Fatty* casts occur chiefly in chronic parenchymatous nephritis. *Blood* casts occur in acute and chronic hemorrhagic ne-

phritis. *Pus* and *bacterial* casts are occasionally met with in suppurative nephritis."—(From Stevens' *Practice.*)

5.

HERPES ZOSTER.	VESICULAR ECZEMA.
1. Follows lines of nerves.	1. No special distribution.
2. Eruption often preceded by intense neuralgic pain.	2. Itching and burning attend outbreak of eruption.
3. Vesicles in groups.	3. No definite arrangement.
4. Vesicles discrete.	4. Generally confluent.
5. Vesicles large and tense.	5. Vesicles small, flaccid.
6. Vesicles do not rupture spontaneously.	6. Vesicles tend to rupture.
7. Eruption unilateral.	7. Usually symmetric.
8. Severe shooting pains during eruption.	8. Variable amount of itching and burning.
9. Tends toward spontaneous recovery.	9. Remains stationary or progresses.

—(From *Cyclopedia of Medicine and Surgery.*)

9. *Excess of sodium chloride in the urine* occurs in: polyuria and during absorption of serous effusions.

Diminution of sodium chloride occurs in: Several of the acute infectious diseases (particularly acute lobar pneumonia), nephritis, yellow atrophy, gastric carcinoma, gastric ulcer, anemia, chorea, idiocy, melancholia.

10. A *physiological leucocytosis* is found: In the newborn, after parturition, after exertion, after a cold bath or massage, during pregnancy, and during digestion.

A *polymorphonuclear leucocytosis* is found in all acute inflammatory diseases, in certain of the acute infectious diseases, and accompanying the cachexia of cancer.

A *lymphocytosis* is found in lymphatic leukemia, and sometimes in sarcoma and whooping cough.

Eosinophilia is found in trichinosis, some bone diseases, some nervous diseases, asthma, emphysema, and eczema.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 14
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Oct. 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	Oct. 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 11
Iowa	Louis A. Thomas, Des Moines	DesMoines	Sept. —
Kansas	F. P. Hatfield, Olathe	Kansas City	Oct. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	Nov. —

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of July 24, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	437	155
Diphtheria	198	24
Measles	423	23
Scarlet Fever	58	6
Smallpox	—	—
Varicella	16	—
Typhoid Fever	71	8
Whooping Cough	49	10
Cerebrospinal Meningitis	3	4
Malarial Fever	..	..
Totals	1,255	230

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 23, 1909:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS
Georgia, Macon	July	4–11	2	.
Indiana, Fort Wayne	June	26–July 3	1	.
Kentucky, Lexington	July	3–10	2	.
Newport	July	3–10	1	.
Louisiana, New Orleans	July	3–10	2	.
Michigan, Grand Rapids	June	5–12	1	.

WHO ARE THE UNFIT?

By CHAS. E. WOODRUFF, M.D.,

SURGEON AND MAJOR, U. S. A.

THE expression "survival of the fittest" has been widely misunderstood. It does not mean survival of the best, but merely those fittest for survival, and they may not be fit for much else. Consequently, when physicians have seen pneumonia and typhoid carry off the robust and leave the feebler, or tuberculosis end the careers of men of great mental ability while stupid dolts recover, or when they contemplate how modern medicine saves weak infants who in former ages invariably perished, there grew up the habit of speaking of the survival of the unfit—a contradiction of terms. Nature is not concerned with the methods chosen, one is as good as another providing the end is attained—survival. Nothing succeeds like success. Consequently, organisms which learn to live at the expense of others, undergo favorable changes fitting them to parasitism and it is the same process of survival of the fittest for survival in that form of the struggle for existence.

It makes no difference whether a man is big or little, stupid or brilliant, if he survives and leaves offspring who in their turn leave descendants, he is fitter for survival than those who perished without leaving offspring. Mere length of life, then, is not the only way of judging of the fittest for survival. Some families may persist even if every member dies before 40 or even 30.

The whole trend of civilization is to preserve every baby born, whether it is strong or weak. In former ages only those who resisted disease could survive as the fittest, and in time a whole race becomes immune to each organism. That form of evolution still continues, though mostly among savages and the lower orders of the higher races, but if a man produces an artificial immunity in lieu of a natural one, he is just as fit for survival. The higher races are being filled up with types which survive by reason of the artificialities of civilization —a process which has been going on ever since clothing replaced body hair, and implements replaced teeth and claws. Therefore, bodily weakness, and inability to withstand attacks of any enemies without artificial assistance, is no proof of unfitness for survival. Indeed, the future race may be mere weaklings compared to present man, and the rage for physical development may be futile, as it creates muscular masses of no special use, except to win harmful marathons, and stand tests of endurance.

There is one form of unfitness which is causing dreadful disability wholly unnoticed—unfitness to climate when there is a migration to a climate markedly different from the ancestral one. Physicians have been so much occupied with those who through infectious disease are unfit to struggle for existence, that they are inclined to overlook the curious states of exhaustion which unfit one for labor and drive the sufferer into vagrancy, crime or pauperism, and it has therefore escaped notice that many of these cases are climatic and differ in no respects from the loss of energy following long residence in the tropics. As we are all far from our ancestral home, it behooves us to study the failures among us, so that we can discover the causes and prevent similar disasters to our grandchildren, if the causes can be avoided.

Previous studies of the nervous and insane have shown that those most out of adjustment to this sunny climate, that is, the blondest, do furnish a higher percentage of cases than they should, or than they do in cloudy places like Scotland. The new studies of criminals and paupers show that there is the same factor at work here too, among the myriad other causes of these unhappy types of human rejects. Similar studies among European criminals have not shown anything of this nature, because the populations are not migrants but are found where they have been from time immemorial. Indeed, in Europe, it has always been customary to think of the criminal type as brunet—burglars, pirates, villains of the drama and "black hags."

Of course, complexion of itself has nothing to do with criminality, yet there is a reason for the popular tendency to consider the offender class as brunet, and the upper types as lighter. The southern drift of population in Europe has always caused an overlaying of brunet southern types, by the bigger, blonder northener who have been the world's brainy races for so long a time, and who have been the aristocrats and law makers.

The poor peasant, then, always had an overload of lighter complexion than himself. The lady in the castle was blonder than the peasant woman in the hut. Centuries and perhaps thousands of years of these conditions, have had the effect of creating the curious impression that what is above us is blonder than we and that which is beneath us is darker. Art and literature have been at work crystallizing it in painting and poetry.

The princess is pictured as a blond, though many of them are dark brunets, good fairies and angels are almost always given yellow hair, and even dolls "made in Germany" are blonds as a rule. The artist paints Christ as a blue-eyed blond, though such types probably did not exist in Palestine. The same rule is found in ancient times. Homer's gods and men were frequently fair, and Venus is generally blond, though occasionally given dark eyes. Milton's Eve was a blond. Greek sculptors quite frequently painted light hair on their statues. Havelock Ellis, in one of his works, mentions many illustrations, showing the admiration for blue-eyed

blonds, among poets, painters and aesthetic writers, from the Renaissance to modern times, not only in Italy but in Spain, France and Germany. The same tendency is shown in the mural decorations of public buildings in America.

The blond being reserved for the ideal in all the virtues, it left the brunet type to represent the lowly and criminal. Mary Magdelane is never a blond, but the Virgin generally is, the thieves on the cross are brunets, but Christ in their midst is blond —and there is a wealth of illustration in folklore art and literature that dark types are used for the villains.

There may have been a basis for this at one time, for the law makers were of a separate blond class from the brunet law breakers. Dr. John Beddoe, the great anthropologist, in his famous Huxley lecture on Color and Race, asserted that there was even now a preponderance of dark hair and brown eyes among English criminals—and England has been noted for the large number of blonds in the aristocracy and the brunetness of the lower layers of society. The ancient *yarl* or *carl* was blond but the *churl* was brunet, and the lower classes filled the prisons as a matter of course, then as now.

In a visit to Clinton Prison, of New York State, where the worst classes of criminals are confined, and where I expected to see the place full of modern "black beards," I was astounded at the large number of blonds—some of them of very light type. It seemed as though the facts as to the brunetness of criminals were the reverse of the popular idea on the subject. Through the kindness of the State Superintendent of Prisons, and the Prison Chaplain, Rev. F. H. Pierce, I was furnished with statistics which confirmed the first impression of the marked blondness of the incorrigible or habitual criminals of this part of the country.

Of the 279 white men whose eye color is mentioned, 144 had blue eyes, 40 gray, hazel and light brown, and only 95 dark shades of brown. The detailed figures show even more conclusively still, that these criminals do not tend to brunetness.

Light blue	6
Blue	17
Dark blue	121
Light gray	1
Gray	11
Dark gray	6
Hazel	2
Light brown	20
Brown	57
Dark brown	34
Black	4

In tabulating these remarkable statistics it was found that the proportionate numbers in each page of figures were practically the same, so that the percentages of the various types would be the same if 1,000 were studied instead of 279. The hair color of 253 was available for comparison and shows a general correspondence with the eye color. There were 19 with very light hair, 61 with light brown and brown, 61 dark brown and only 112 black. The details were as follows:

Chestnut	2
Blond	2
Light blond	2
Sandy	6
Red	7
Light brown	16
Brown	45
Dark brown	61
Black	112

It is quite difficult to classify men as to their relative pigmentation. Indeed, medium types would be called brunet by one observer and blond by another. Taking everything into consideration, it would perhaps be safe to classify them as follows:

Light blond	16
Blonds	116
Light brunets	107
Dark brunets	41
Very dark brunets	6

If the very dark brunet is classified as 10, and the lightest yellow-haired blond as 1, they would fall into the following classes:

Class.	Number.	
1	0	Light blonds.
2	3	
3	13	
4	17	Blonds.
5	30	
6	69	
7	61	Light brunets.
8	46	
9	41	Dark Brunet.
10	6	Very dark brunets.

Thus the two extremes, of very dark brunets and very light blonds, such as the typical swarthy Italian and the yellow-haired Scandinavian, are in a decided minority, but the medium types tend strongly to blondness.

There are no reliable statistics by means of which these criminals may be compared with the general population. It is safe to say, nevertheless, that blonds do not constitute anywhere near half of our population, which is notoriously brunet with brown or gray eyes and dark hair in decided preponderance.

The explanation of this local phenomenon is as follows. Criminologists are quite of opinion that there is no criminal type, but that there is an instability of the nervous system or neurasthenia which is the basis of habitual crime. Hence in America we find more nervous instability among the blond types and more of them drift into crime as a result. In many other ways they prove their unfitness for these southern climates, notably an increased susceptibility to disease—particularly tuberculosis. In Clinton Prison 83 per cent. of the tuberculous criminals are native born.

Light affects the young far more than it does the parents. Hence blond adult immigrants may remain in fair health, but the deterioration begins in the next generation. Therefore we should not expect to find very many foreign born among these blond criminals. The report of the Superintendent of New York prisons shows that only 22 per cent. of the criminals in Clinton Prison are foreign born, and most of these foreigners are from brunet countries like Italy, Poland and Russia. Very few come from blond countries, for only five were born in Scotland, one in Sweden, and none in Norway. The native-born therefore furnish the great majority of the blue-eyed professional habitual criminals in New York.

This is in marked contrast to the fact that the standard of morality is vastly different among the blond types of northern Europe than it is among the brunets of the Mediterranean, where crimes of violence seem to be everyday affairs. These brunets do not furnish their share of habitual criminals, but they do furnish a large proportion of the first offenders in Sing Sing where 43 per cent. are foreign born—double the percentage in Clinton Prison. In Sing Sing these foreigners also are to a large extent from brunet countries like Italy and Russia. The blond countries furnish very few. Norway, 2;

Sweden, 7, and Scotland, 7, in a total of 533 reported. Hence crimes against the person predominate in Sing Sing, but in Clinton Prison, where there are so many native born, crimes against property greatly predominate. That is, the neurasthenic, blue-eyed native criminal cannot stand the stress of the struggle of existence and resorts to crime to live. The foreign born, though constituting 26 per cent. of the population of New York State in 1900, commits too many crimes of violence and constitutes nearly half of Sing Sing, but it does not resort to crime as a profession or habit so often as the native born.

The tendency to blondness is not confined to the older criminals but is found also in the young offender, for his criminality is a positive indication of family degeneration—the types which for one reason or another, are failing in the struggle for existence. The new immigrants are still healthy, as they have not had sufficient time to deteriorate even if they will at all. Consequently we find that 70 per cent. of the young criminals admitted to the Elmira Reformatory are native born, and over half of these had native-born parents. As most of the committments (82 per cent.) are from Greater New York, with its tremendous foreign population, it is quite evident that the young natives are committing far more than their share of crime.

That their abnormal conduct is due to degeneration of dying families is quite evident from the statistics published. Thirteen per cent. were orphans, 36 per cent. had lost father and 30 per cent. mother. An enormous number had physical defects or diseases and 30 per cent. were mentally defective, over half were intemperate, three-fourths used tobacco and 2½ per cent. used drugs. Among their parents, 10 per cent. had mental disease, about one-third were drunkards and one-half had little or no education. The children were about the same as the parents, or worse, perhaps, for 62 per cent. had little or no education, and less than 5 per cent. were able to reach the high school.

It takes time for the environment to cause such degeneration, consequently the young criminal comes from the types which have been here the longest, and these are much blonder than the foreign born, as a class. The following are statistics of about 5,000 men, whose average age was less than 21 when admitted to Elmira. The data have been kindly furnished me by the resident physician, Dr. Frank L. Christian. As 30 per cent. are foreign born and about 35 per cent. are natives born of foreign parents, and as these two classes are notoriously black-haired, dark-eyed brunets, the statistics should show a great preponderance of brunets—but they tend to the opposite. The blond native born, of native or foreign parents, seems to preponderate in accordance with the rule of decadence of the lighter types.

COMPLEXION		HAIR		EYES	
Sandy	52	Blond	318	Blue	1,305
Light	608	Red	90	Greenish	861
Medium	2,941	Sandy	103	Yellowish	276
Dark	940	Light brown	1,203	Gray	456
		Dark brown	1,449	Slate	430
	4,631	Black	1,400	Light brown	631
				Dark brown	505
			4,569	Black	68
		(Gray omitted.)			4,631

Out of 4,631 young offenders there are only 68 with black eyes and only 505 with dark brown. Even taking in the light brown, all these dark types constitute but one-fourth the total, the medium types of gray and slate are one-fifth and the light-eyed more than half.

In one prison in a Western State where there is a large foreign population, largely blond, nearly all the criminals are native born. Curiously enough, also, most criminals the world over come from healthy, respectable families.

Undue criminality is merely one of the many ways in which the blond types disappear when they migrate too far from their original home. It is regrettable that so little attention has been given to the underlying pathology of crime, for little headway can be made in prevention, as long as we all feel that it is a mere matter of teaching. Perhaps this study may stimulate inquiries as to the reason why the same unfortunate environment will make scoundrels of some boys and hard-working honest men of others, and why a moral home may turn out so many criminals. Too often it is a matter of defective development, from bad food and bad housing, but climatic factors are also at work as these statistics prove.

Old criminals are often incorrigible, but the young are generally curable if the causes are removed and normal development ensues, so let the causes be found.

The very worst of the unfit are the aged paupers who have no friends or relatives to support them, who have made no provision for old age, and who promptly perished in former times. A study of 602 on Blackwell's Island developed the following amazing results to eye color:

Light blue	220
Dark blue	125
Gray	170
Light brown	57
Dark brown	30
	602

Only one-fourth of these were native born, half were Irish, about one-fifth German and the rest scattering. Alcohol was almost invariably the determining cause of the disability, and it shows that the underlying nervous cause of alcoholism is far more prevalent in blonds than in brunets in New York City. I have learned of a study of some 40 or 50 healthy, strong Irish immigrants of the year 1840 whose descendants showed a dreadful record of alcoholism and who are rapidly dying out. The thirst for alcohol is merely the expression of a nervous weakness acquired under America's sunny skies, and resulting from excessive stimulation of light as one of the thousand other causes.

It seems remarkable that of 602 aged paupers of a notoriously brunet city, only 30 had dark-brown eyes, and it is evident that the brunet population is able to struggle for existence more successfully, and lay up funds for support in old age or raise families who are vigorous enough to support the old folks. The above statistics were kindly furnished me by the former Deputy Superintendent, Mr. Joseph D. Flick.

Of 90 paupers in Boston institutions, we find the same general trend in a city markedly more blond than New York; light blue, 27; dark blue, 25; gray, 22; light brown, 10; dark brown, 6.

It is to be hoped than when the new farm colony for vagrants is established, an effort will be made to determine what manner of men they are, so that preventive means may be adopted. At present we have nothing reliable in the way of statistics, beyond some very general observations in some parts

of our south, where the "low white trash," who are so lacking in energy and neurasthenic, seem to be much more blond than the normal, vigorous population.

Unfavorable climatic factors then are causing unfitness for survival in the types too far misplaced, and the process differs in no respect whatever from that found in all other species of migrated plants and animals. The unfittest for ultimate survival may be those which we formerly considered the best of our immigrants. The "worst" types from Southern Europe may survive permanently for they are not so greatly out of adjustment, indeed, the climate selection may not differ at all from the ancestral one. They may hold a carnival of murder and crimes of violence, but if they survive in health and are self-supporting, and keep out of the poor house, they are the fittest for survival and the brainy, brawny, disappearing blond the unfittest. If, on the other hand, the blond finds the causes of the lack of efficiency and higher death rate and avoids them, he is just as fit for survival as any one else, and will prove it by surviving. But the present production of paupers, criminals and nervous wrecks among them will continue as long as the medical profession scouts the idea that we are out of adjustment to this southern latitude—so vastly different from the cloudy ancestral home in northwestern Europe—and continues to sing the praises of the sunshine which causes the damage.

TUBERCULOSIS OF THE PERICARDIUM CURED BY INCISION AND DRAINAGE.*

By C. L. GIBSON, M.D.,

NEW YORK,

SURGEON ST. LUKE'S HOSPITAL.

The operative relief of any form of suppuration within the pericardial sac seems to be quite uncommon. Eliot (*Annals of Surgery*, January, 1909) says: "The literature of purulent pericarditis has been admirably collated by Roberts and C. B. Porter. By the former surgeon 37 instances of operation for that condition were tabulated from different sources in 1897, and to that number 10 additional cases reported in the literature between 1897 and April, 1900, were added by Porter." Eliot, in addition to his own case, reports 20 published since Porter's contribution in 1900. So that in the beginning of 1909 the recorded number of operations would seem to be only 68.

Operations, if any, for the relief of tuberculous percarditis must be rare, and the fact that a cure was obtained in the case here reported gives it special interest. No mention at all is made of tuberculosis in Eliot's contribution. The history is as follows:

W. B., negro, 26, married, laborer, entered St. Luke's Hospital July 13, 1908, service of Dr. Theodore C. Janeway. Family history for tuberculosis is negative. Past history is without features except for an ischiorectal abscess three months ago.

Present illness: For the past two months has had a heavy cough with slight expectoration. For the past two weeks dyspnea has been so bad that he could not lie down, sleeping in a chair. Swelling of the feet noted six days ago.

Physical examination showed: Colored man of fairly large frame, fairly well nourished. Breathing with some difficulty and with an expiratory grunt. Heart percusses 1½ in. to *right* of sternum and 6 in. to left. Sounds are of poor quality and hard to hear. Considerable bronchitis.

Blood examination: White blood corpuscles, 8,300; polynuclears, 69 per cent; lymphocytes, 29½ per cent; eosinophiles 1½ per cent. Temperature elevations up to 102°.

Five days after admission it is noted: "Pericardium was aspirated in fifth space, 4 inches to left of median line; 18 ounces of opaque, yellowish fluid were obtained. Before aspiration, heart dullness extended 5 inches to left in third space, 6½ inches to left in fifth space, 1½ inches to *right* in the third space, and 2 inches to right in fourth space. Area of cardiac dullness was greatly diminished by the aspiration. Blood pressure in early part of aspiration was 80 mm., subsequent to aspiration, 95 mm."

The report of the pathological laboratory was negative as regards the etiological source of the fluid.

The next day the patient's general condition showed improvement, but there was a rising temperature and rapid increase of cardiac dullness. Dr. Janeway kindly asked me to see him with a view to operative relief, to which I readily agreed as necessary to avert a fatal termination of the condition.

Operation, July 19, 1908: Attempts at local anesthesia were resisted by the patient; but it would be perfectly possible to perform this simple operation in a patient of ordinary self-control. Chloroform was given to the point of producing unconsciousness, then followed by ether.

Incision in the long axis of the left fifth cartilage, which with a bit of the rib was removed by rongeur forceps; more room seeming desirable and the patient's condition being satisfactory, the fourth cartilage was also removed. The exposure was admirable and made the subsequent steps simple and easy. Neither the presence of the pleura nor that legendary bugbear, the internal mammary artery, had to be considered. The greatly distended pericardium was seized between two Kocher clamps and a two-finger incision gave issue to a great volume of pus, probably a quart; but as the pulse at the same time weakened perceptibly the flow was checked by blocking the exit in part, with appreciable good effect. The sac must have contained some three quarts. The pericardial edges were sutured to the soft parts and a rubber drainage tube passed into each lateral cul-de-sac.

At the close of the operation the patient was in good condition, with improved quality of pulse. While remaining pretty sick for some days the patient improved steadily. The drainage was profuse. The tubes were removed in a week; Sept. 9, 1908, transferred back to the medical side. Wound entirely healed without sinus.

Since the operation his general condition has been poor, and he has been readmitted to the hospital several times. He is now (May, 1909) an inmate of the tuberculosis ward, the presence of a tuberculous process in the lung being now manifest. Tubercle bacilli were not found till recently, notwithstanding almost daily examination of the sputum.

The pericardial healing has persisted, evidences of an adhesive process being manifest. While no positive laboratory findings exist to confirm the diagnosis, there is the negative evidence of failure to cultivate other pus-producing organisms. The process did not develop as a sequel to rheumatism or pneumonia. It is not the incidental pericarditis

*Read before the American Surgical Association, June 4, 1909.

sometimes seen with extensive pulmonary tuberculosis, as the process in the lungs now present did not develop till some six months later. The character of the pus evacuated was obviously of tubercular nature in the opinion of all who saw it. The low leucocyte count with normal polynuclear percentage would also strongly favor a tubercular rather than one of the usual pyogenic infections.

That such a severe process can result in a cure in the face of an advancing tuberculous diathesis is certainly remarkable, and this experience should justify us in applying surgical measures to this condition.

THE OPHTHALMOTUBERCULIN REACTION.

By JOHN R. HICKS, M.D.,
NEW BRIGHTON, R. B.
NEW YORK.

I HAVE applied the ophthalmotuberculin test for tuberculosis in a number of cases with varying results. After trying various methods of technique it seems to me that all methods I have seen are faulty in that no attempt has been made to sterilize the eye before using the test.

Practically all serum tests are made with sterile solutions applied in an aseptic manner.

Not rarely if a culture is taken from the conjunctiva planted upon the blood serum and encubated for twenty-four hours numerous forms of bacteria may be isolated and described. The *Diplococcus lanceolatus* occurs in the oral cavities and conjunctiva of about 20 per cent. of healthy persons and often it is the cause of ulcer of the cornea. Severe types of corneal ulcer have followed the tuberculin test, their description being a typical picture of an ulcer of the cornea produced by the *Diplococcus lanceolatus* of pneumonia. Other organisms known to produce corneal ulcer are *Staphylococcus pyogenes aureus, albus, citreus,* and *epidermidis albus,* the streptococci in their many strains, the gonococcus, and other microorganisms. If the eye is not sterile before applying the ophthalmotuberculin test I cannot see how one can say that there is a specific action on the conjunctiva of the tuberculin when pyogenic or other organisms are present, only waiting for some suitable soil, a congested or irritated membrane, made so by the solution of tuberculin, to develop and excite a severe inflammation of some part of the eye.

Tuberculin, wind, dust, or a minute foreign body, may be the starting point of a conjunctivitis or, more properly, a hyperemia of the conjunctiva, but no true inflammation or corneal ulcer will result unless pyogenic organisms are present. A sterile foreign body, as a small piece of cinder out of a furnace, will produce this severe irritation of the conjunctiva and cornea which by infection with pyogenic organisms may result in an ulcer, but a sterile cinder will not produce a true ulcer in a sterile eye.

Impaired nutrition of the cornea due to many general diseases, viz., tuberculosis, typhoid fever, measles, anemia, etc., may be complicated with corneal ulcer, but there will be no true ulcer unless there is true infection except in the so-called neuropathic conditions of the cornea due to disturbance of the trophic nerve supply.

I have sterilized the eye and applied the tuberculin solution in double the strength advised and have gotten no reaction, when on the other hand without sterilization I would get quite a violent reaction.

The method of sterilizing the eye preparatory to using the tuberculin test is as follows: For four days the patient's brow and face are washed with soap and water three times a day and 1-8000 solution of bichloride of mercury dropped into the eye after each washing. At the end of six days a culture is taken just as in diphtheria and incubated. If at the end of twenty-four hours or longer there are any colonies the bichloride solution is resumed for two days, then the eye is irrigated for two days more twice a day with physiological saline solution to wash away the bichloride and any organisms remaining. The next morning another culture is taken and incubated for twenty-four hours and cover slide preparations are made and examined and if no organisms are found the tuberculin test is made in the usual way. The eye after irrigation with saline solution is bandaged the afternoon before to keep foreign substances out. I have failed to get any specific reaction in a number of cases when the test is applied in the above way, when without sterilization I have gotten the reaction in Bright's disease when there was no reason to suspect tuberculosis.

It may be said that the bichloride solution prohibits the reaction, but it does not seem probable if the eye is irrigated with saline solution for two days before applying the test. I think this paper applies to the nasal test as well as the eye. It is very probable that the dangerous reactions are due to lack of cleanliness and secondary infection.

BRAIN TUMOR WITH UNUSUAL SYMPTOMS.

By J. E. DALE, M.D.,
FORT COLLINS, COLORADO.

THE patient was a lad, 16 years old, a high school student, well nourished, of nervous, energetic temperament. He had had the ordinary diseases of childhood. His home surroundings were good, the father was healthy, the mother was neurasthenic; one brother, two years younger than himself, was perfectly healthy.

I first saw the patient July 7, 1908. The previous day he had suffered from what was apparently an attack of acute indigestion, vomiting repeatedly during the night and fainting on one trip to the bathroom. His mother stated that she had taken his temperature at this time and it was "above normal."

When seen on July 7, the pulse was 75, temperature 97°, occasional vomiting, abdomen tender to touch. There was no headache. After the bowels were cleaned out vomiting ceased, but the temperature remained subnormal. Further than this a careful examination was negative.

He was kept under observation for the following month, during which time no abnormality could be found except temperature which varied from 96° to 97.5°. The Widal reaction, and the ophthalmic tuberculin reaction were negative; the reflexes were normal; there was no headache. In August he developed an obstinate constipation, apparently due to lack of peristaltic action. On September 3 there was a second acute attack, similar to the first, only more severe; by September 4 there was marked dullness over the sigmoid flexure. On September 5 and 6 there was a very little occult blood in the

passages, with tenesmus and straining when bowels moved.

As soon as the colon was cleared by a high enema the patient improved and in a few days returned to school. During this attack the temperature did not at any time go higher than 97.5°. The pulse varied from 70 to 80. There was no headache at any time. Dr. Kickland, of this place, saw him in consultation at this time.

There were no further abnormal symptoms except subnormal temperature up to September 26, when the patient reported at my office about noon, saying he was well, but felt as if he could not breathe—as he expressed it: "I have to make myself breathe, and I feel as if I could not do it." A careful examination of the lungs and heart was negative. The temperature was 97°, the pulse 76, and the respiration 19. That evening at nine he was seen at his home. The temperature, respiration, and pulse were the same, but vomiting had begun, and he complained still more of the difficult breathing. The condition was unchanged on September 27. The bowels moved only by use of enema. The catheter was used once late on that day, when 10 ounces of normal urine were obtained. After this the urine was voided naturally. On the morning of September 28 the temperature, pulse, and respirations were practically unchanged; he still complained of difficulty in breathing; his expression was anxious. The patient was very nervous and there was occasional slight vomiting. Dr. Kickland again saw the patient; further consultation was asked for, and Dr. J. N. Hall, of Denver, was called, but death occurred before he arrived.

At 1.30 P.M. (the 28th) the temperature was 97°, the pulse 78, the respirations 20 and to all appearances normal, but the patient complained bitterly of difficulty in breathing. The pupils reacted promptly to light. The condition was unchanged up to 3 P. M., when the breathing very suddenly became more shallow and slower. The patient became unconscious in a few minutes. The left eye was closed, the pupil contracted, the right eye open, the pupil dilated. The mouth was drawn to the left. Marked cyanosis rapidly developed, becoming more and more intense. There was no further movement except slight twitching of the left side of the face. The pulse remained normal up to a few minutes before death, which occurred one hour after first appearance of paralytic symptoms.

Autopsy.—The brain was removed and sectioned. Attached to the roof of the fourth ventricle, slightly to the right of the median line and directly over a point in the floor slightly posterior to the center, was a growth about one centimeter in diameter, somewhat pedunculated, the surface rough, about the color of the surrounding tissue, macroscopically resembling a villous wart. In the substance of the cerebellum about the base of the tumor for a distance of two centimeters or more the outline of the arborvitæ was blurred and indistinct. The specimen was submitted to Dr. B. F. Kaup, pathologist to the Colorado Agricultural College, whose report is as follows:

"The growth is an endothelioma of the type in which the endothelial cells lie in close concentric rings about the blood-vessels. It does not involve the brain substance, but is confined to the membrane, the changes noted in the cerebellar substance being due to a leucocytic infiltration." The writer's thanks are due to Dr. Kaup for the examination.

Conclusions.—It will be noted that there was entire absence of the usual headache symptoms. The late effect on the respiratory center was to be expected from the situation of the tumor. In this connection it should be stated that the body had been injected with formaline before permission to hold an autopsy was obtained, and in all probability there was some shrinking or contraction of the growth from this agent. Unless from the leucocytic infiltration, the early and constant effect upon the heat centers is hard to explain.

140 West Oak Street.

MUMPS VS. TETANUS. A CLINICAL NOTE.

By DAVID I. MACHT, A.B., M.D.,

BALTIMORE, MD.

ASSISTANT IN MEDICINE, JOHNS HOPKINS HOSPITAL.

The following interesting case is, I think, unusual enough to be worth reporting.

Patient, S. F., 22 years old, student, came to me on March 7th with an infection of the right hand. He gave a history of having some five or seven days previously stuck a dirty needle in his wrist. On examination it was found that the patient had a pretty extensive cellulitis of the dorsum of his right wrist. This was incised, drained, packed with iodoform gauze, and bandaged. The following day the wound was healing nicely but the patient claimed to have felt pretty sick and to be unable to attend to his studies. To this I paid no attention, as I attributed the trouble to nervousness and slight shock after the operation, without any local anesthetic.

On March 9th, the third day after the operation, and about ten days after the original infection, I was hurriedly summoned to see the patient at home. The patient complained of stiffness in the jaws and slight pain in neck and back. On examination, patient was found to have a slight fever. Temperature, 99.5, with pulse to correspond. Throat, negative; chest and lungs clear on percussion and auscultation; heart, negative; sounds, clear; abdomen, negative; liver and spleen, not enlarged. The jaws felt rather stiff, no tenderness; right-hand wound closing and healing nicely; no inflamed lymphatics; cubital and axillary glands not enlarged or tender.

The history of the case, the presence of a puncture-wound over a week old, and the symptoms developing, made me very anxious. The first thought was naturally of tetanus or lock-jaw. The patient was ordered to bed and the same afternoon I administered 1500 units of tetanus anti-toxin hypodermically in the skin of the abdomen. On the following day the patient began to show some interesting features: Temperature, 100.1° F.; pulse, 100. The region about the angle of the left jaw was distinctly swollen and tender, and there was a slight fullness on the right side. In a few hours the swelling increased and the patient presented a picture of a typical epidemic parotitis or mumps! The subsequent history of the case is not remarkable. The patient had rather slight fever and the swelling increased. There was a dysphagia. Patient was kept in bed and under ordinary treatment made an uneventful recovery in about a week's time. There were no complications.

The case is interesting because of the curious combination of two distinct infections, the puncture wound of the hand and parotitis. Of course, when either disease is fully developed tetanus and mumps

could never be confounded with each other. In tetanus we have no swelling of the parotids. There is merely stiffness of the jaw muscles and the muscles of the neck and back with an extreme hypersensitiveness of the nervous system. In mumps we have a distinct swelling and tenderness of the parotids which makes a picture of the disease easily diagnosible at a glance. But at an early stage, as in the present instance, great difficulty in diagnosis may occasionally arise, and the above case is but another instance of how the simplest diseases may sometimes cause the greatest anxiety to the general practitioner.

1511 Madison Avenue.

THE UNRELIABILITY OF MEASUREMENTS OF ANCIENT SKULLS.

By A. L. BENEDICT, A.M., M.D.,

BUFFALO, N. Y.

The exploration of an ossuary of the Neuters, a tribe of Iroquois independent of the Five Nations, has recently again called my attention to the necessity of offering a criticism on various statistic and descriptive articles dealing with craniology and similar mensurative studies of ancient bones. This ossuary contained somewhere between 300 and 500 skeletons and represented one of the (probably approximately) decennial collections and interments of remains previously exposed on scaffolds and in trees. From the entire lack of implements, it is probable that the date of this ossuary was earlier than 1620, by which time articles of European manufacture were fairly common among the northeastern Indians, and this opinion was confirmed by the relatively greater degree of decay of the bones, as compared with skeletons found in graves of the period of European influence but adjacent to villages known to have been destroyed in 1687, the soil, climate, and depth of burial being approximately the same.

Any one who has had much experience in the exhumation of Indian skeletons is familiar with the fact that the pressure of the earth, alternate thawing and freezing, the moisture of the soil, and the drying after removal and storage in museums, produce considerable changes in the shape of the skull. In young subjects, the sutures are often more or less separated so as to allow molding of the cranium in various ways, and in infants and very young children the skull is usually pretty well disarticulated. Doubtless analogous changes occur in other bones, but they are not so conspicuous and are not so apt to be made the basis of pseudo-scientific articles. While gross anatomical features are often well preserved for many centuries, especially in cave burials, any nice determination of angles, ratio of diameters, etc., is fallacious.

In this connection, the attention of osteologists is called to the fact that no study on a sufficient scale has been undertaken to determine the ratio of the length of particular bones to the height of the body. It is well known that the ratio varies considerably, but it would be of value to ethnologists to know the maximum and minimum ratios and the percentage of instances in which an average ratio holds good, as applied, for example to the femur and the other long bones of the limbs. It may be stated that it is quite impossible to judge the height of the body from a reposition of the disarticulated skeleton and, as Indians were very seldom buried in full extension, the measurement from skull to feet, in the grave, is not available. However, it may be said that Indian skeletons are very rarely of great stature.

One of the skulls found at the ossuary mentioned (Sweeney farm, near Gasport, N. Y., May 18 and 19, 1909) afforded a basis for criticism of a very elaborate study of deviations of the nasal septum, based on Canadian museum specimens that appeared a few years ago. A large pebble had crowded the septum far to one side. On removing this, the septum was quite freely movable, as long as the skull remained damp, and even amenable to plastic manipulations. As pebbles and dirt are almost always found in the facial apertures of buried skulls, it is obvious that only the most careful investigation, at the time of exhumation, with elimination of extrinsic factors, could render any such study of value.

TABULAR REPORT OF CASES OF CANCER TREATED WITH TRYPSIN.*

By WILLIAM SEAMAN BAINBRIDGE, M.D.,

NEW YORK.

In the cases which follow only such details are given as have a bearing upon the blood examinations. For all other data the reader is referred to the accompanying table, in which we have endeavored to give the essential facts concerning each case.

Case 33.—Carcinoma of Uterus and Abdominal Viscera. Patient was first given glycerin and sterile water injections for nine days, with no subjective or objective results. She was then given alternate injections of trypsin and amylopsin from December 21, 1907, to January 24, 1908, and from that time irregularly to February 20. Ten days after beginning the regular enzyme treatment the blood showed hemoglobin 60 per cent., few normoblasts, microcytes and pale red cells. Total white blood count 22,000. This ranged between 22,000 and 29,500 per cubic millimeter. Polymorphonuclear cells relatively and absolutely much increased, numbering 25,549 per cubic millimeter two weeks before death. There was a relative decrease in small mononuclears, the total number, however, varying from normal to 1,800 per cubic millimeter above normal. The eosinophiles steadily increased from 408 to 1408 per cubic millimeter one week before death. Hemoglobin at this stage 51 per cent. The rapid decline of the patient during the course of the treatment was doubtless due to the advanced stage of the disease rather than to the treatment.

Case 50.—Carcinoma of Breast; Operable; Operation Refused. Trypsin and amylopsin given alternately from December 7, 1907, to January 6, 1908. On account of an attack of acute influenza, with coincidental abscess formation at the site of one of the injections, treatment was suspended until February 11, 1908, when it was resumed and continued until February 26. Internal treatment with Holadin and ox-gall given continuously from December 7 to February 26. While on the treatment the total white cell count varied between 6,500 and 10,500 per cubic millimeter. The small and large mononuclears fluctuated relatively above normal. The eosinophiles, which were 78 per cubic millimeter in a count made before beginning the treatment, were 040 per cubic millimeter the day of discharge from the hospital.

Case 78.—Recurrent Carcinoma of the Left Breast, and Supraclavicular and Infraclavicular Glands, following amputation. Regular enzyme

Case	Name	Sex	Age	Nationality	Color	Single Married	Occupation	Private or Hospital	Referred by or in Consultation with	Diagnosis: 1 Clinical 2 Microscopic	Location of Disease	Duration of Disease Previous to Enzyme Treatment
1	L. H. B.	M.	38	U. S.	White.	Married	Salesman.	Private.		1 Carcinoma 2 Squamous-celled carcinoma.	Primary: Tongue and glands of neck. Secondary: Floor of mouth and neck.	1½ years.
2	M. R.	M.	39	German-American	White.	Married	Cab driver.	Hospital	Wm. T. Bull, N. Y. City.	1 Carcinoma 2 Carcinoma	Tongue and glands of neck.	1½ years.
3	B. V.	M.	68	German.	White.	Married	Tailor.	Hospital.	Fred Wise, N. Y. City.	1 Carcinoma 2 Carcinoma	Bladder and prostate.	9 months.
4	I. L.	F.	38	U. S.	White.	Married	Housewife.	Hospital.		1 Carcinoma 2 Carcinoma	Right breast.	1 year.
5	T. E. W.	F.	44	U. S.	White.	Married	Housewife.	Private.		1 Carcinoma. 2 Carcinoma.	Primary: Uterus. Secondary: Abdominal viscera.	15 months.
6	E. M. P.	F.	56	U. S.	White.	Married	Housewife.	Private.	J. Walker, Brooklyn, N. Y.	1 Carcinoma. 2 Carcinoma.	Uterus, part of vaginal wall and bladder.	About 2 years
7	K. H.	F.	49.	U. S.	White.	Single.		Private.	Edward W. Peet, N. Y. City.	1 Carcinoma. 2 Carcinoma.	Primary: Left breast. Secondary: Contiguous skin, axillary glands, chest wall, neck, pleura, lungs, abdominal organs	About 3 years
8	W. K.	F.	72	U. S.	White.	Married	Housewife.	Private.	L. Nevin, Jersey City, N. J.	1 Carcinoma. 2 Carcinoma.	Uterus, broad ligaments and bladder.	About 1 year.
9	C. J. W.	F.	51	U. S.	White.	Married	Housewife.	Private.	E. O. Palmer, Hollywood, Cal.	1 Carcinoma. 2 Carcinoma.	Primary: Left breast. Secondary: Skin over primary seat; glands of neck and axilla; probably liver.	15 months.
10	J. L. S.	F.	51	U. S.	White.	Married	Housewife.	Private.	J. H. Jenkin, Shrub Oak, N. Y	1 Carcinoma. 2 Carcinoma.	Body of uterus, broad ligaments, glands of pelvis.	2½ months.
11	M. J. B.	M.	70	U. S.	White.	Married		Private.	A. V. Rockwell, N. Y. City.	1 Carcinoma.	Stomach.	6 months.
12	M. A. S.	F.	78	U. S.	White.	Single.	Teacher.	Private.	F. S. Emerson, Brooklyn, N. Y.	1 Carcinoma. 2 Carcinoma of scirrhus type.	Right breast, glands of neck and axilla.	9 yrs. small tumor in breast; 2 yrs active growth.
13	J. I.	M.	37	U. S.	White.	Married	Mason.	Hospital.	E. F. Gissler, Brooklyn, N. Y.	1 Carcinoma. 2 Carcinoma.	Primary: Lower lip. Secondary: Lower lip, lower jaw, glands of neck.	2½ years.
14	S. G.	M.	35	Russia	White.	Married	Tailor.	Hospital.	Max Einhorn, N. Y. City. Henry Franciscus, Brooklyn, N. Y.	1 Carcinoma.	Lower part of esophagus and stomach.	9 months.
15	J. V.	M.	44	German.	White.	Married		Hospital.		1 Carcinoma. 2 Carcinoma.	Primary: Lower lip. Secondary: Lower lip, glands of neck.	8 months.
16	J. K.	M.	43	Bohemian.	White.	Married	Bricklayer.	Hospital.		1 Carcinoma. 2 Squamous-celled epithelioma.	Penis and inguinal glands	6 months.

Previous Treatment	Condition When Enzyme Treatment Was Begun	Duration of Enzyme Treatment	Effect Upon: 1 Local Condition, 2 General Condition, 3 Fetor; 4 Pain, 5 Progress of the Disease.	Result
Antisyphilitic for 1 year (other physicians). Removal of glands of neck, Mar. 9, 1907; removal of left half and part of right half of floor of mouth and left half of tongue, Mar. 27, 1907 (Bainbridge).	Recurrence in floor of mouth and neck. Inoperable.	June 1, to July 12, 1907. Large doses, full regime.	1 Hastened breaking down of tissue, assisted in cleansing 2 None. 3 Slightly lessened. 4 None. 5 None.	Died Sept. 15, 1907.
Five operations for removal of glands of neck and part of tongue (Dr. W. T. Bull).	Recurrence in tissues of neck Inoperable.	Apr 25 to June 29, 1907. Large doses, full regime.	1 Wound became cleaner and diminished in size by one-third during early part of treatment 2 None. 3 Lessened. 4 None. 5 None.	Died July 10, 1907.
Internal medication and *x* ray (another hospital). Refused operation for three months while on enzyme treatment, then suprapubic cystotomy (another hospital). Leucodescent light concurrently with enzyme treatment.	Hematuria. Pain in region of bladder and prostate, very severe on urination; emaciated, weak	Feb. 27 to June 2, 1907. Large doses caused chills.	Negative in all respects.	Died June 12, 1907
Complete amputation of breast (another hospital).	Recurrence in scar; ulceration. Refused further operation.	May 2 to July 15, 1907	1 None. 2 Temporary marked improvement. 3 None. 4 None. 5 None.	Died Feb. 15, 1908.
Hysterectomy (Bainbridge), June 29, 1906.	Recurrence in abdominal viscera Constant pain; hemorrhage from rectum.	Apr. 23 to June 12, 1907. Large doses, full regime.	1 Temporary apparent improvement. 2 Gained in weight at first, temporary general improvement. 3 Lessened. 4 Lessened at first. 5 None.	Died June 18, 1907.
Trypsin powder locally, 1 mo.; curettage; trypsin and amylopsin in very small doses irregularly for 8 weeks; methylene blue for 2 mo. (other physicians)	Inoperable. Suffering from toxemia due to absorption of cancerous products. General condition very poor.	Dec. 11, 1906, to May 17, 1907. Full treatment.	Temporary improvement in both local and general condition, followed by rapid decline. Tendency to non-absorption of large doses of trypsin, resulting in a few so-called abscesses, which necessitated discontinuance of treatment for a few days at the time.	Died May 19, 1907
Removal of growth from left breast, June 4, 1904 (Dr. Edward W. Peet), radical operation refused. About 1 year later, 32 *x*-ray treatments (Dr. Wm. J. Morton); trypsin, 5 to 10 minim doses, Apr. 27 to Oct. 31, 1906 (Dr. Morton). Radical operation, Nov. 3, 1906, (Bainbridge). Removal of enlarged nodules and secondary deposits in skin, Jan. 22, 1907 (Bainbridge).	Full enzyme treatment instituted twenty-four days after radical operation. Recurrent; irremovable cancer of left side of chest and glands of neck, liver enlarged probably cancerous; general condition poor.	Nov 27, 1906 to Mar. 20, 1907. Full regime, with increasing doses of trypsin and amylopsin.	1 Ulcerated surfaces cleared up by lotio pancreatis. 2 None. 3 None. 4 None. 5 Did not prevent recurrence or otherwise influence the disease.	Died Mar. 23, 1907.
Curettage; small doses trypsin for 20 days (Nevin).	Irremovable cancer of uterus, broad ligaments and bladder.	Feb. 2 to Mar. 23, 1907.	1 Temporary apparent improvement. 2 Temporary apparent improvement. 3 Lessened at first. 4 Lessened at first. 5 None.	Died Mar 25, 1907.
Removal of primary growth in breast, Jan. 2, 1906 (another surgeon). Removal of glands of neck and axilla, Jan. 31, 1907 (Bainbridge).	Enzyme treatment begun immediately after removal of glands of neck and axilla. Liver enlarged probably cancerous. General condition very poor.	Jan 24 to Apr. 14, 1907.	Negative in all respects.	Died Sept 1, 1907.
"Kilmer" cancer treatment 4 weeks. Opiates.	Irremovable cancer	Apr. 14 to May 15, 1907	Negative in all respects	Died May 26, 1907.
Medical treatment . .	Usual symptoms of cancer of stomach.	Apr. 8 to 15, 1907 . .	Negative in all respects	Died Apr. 20, 1907.
Palliative. Refused operation for 15 mo. after active growth of disease. Removal of breast and enlarged glands, Apr. 27, 1907 (Bainbridge).	Operable cancer of right breast with area of ulceration about size of fifty-cent piece. Glands in neck and axilla enlarged.	Dec. 19, 1906 to Jan. 22, 1907. Returned home, treatment continued for 3 months.	1 Ulcerating surface cleaned. 2 Temporary slight improvement. 3 No fetor present. 4 No pain. 5 None	Died May 17, 1904.
Pastes, cauterization; removal of growth on lip; "Curry treatment" (other physicians). Trypsin, 10 minims every other day, June 15 to July 15, 1907 (other physician).	Large, discharging mass involving entire lower jaw and glands of neck.	July 15 to Sept. 1, 1907. Full treatment.	Negative in all respects	Died Sept. 20, 1907.
Radium for 3 weeks (another physician)	Emaciated, great pain, dysphagia Operation refused	Mar 24 to June 21, 1907.	Temporary improvement in general condition, dysphagia less marked. Later grew rapidly worse.	Died Sept 15, 1907.
Primary growth removed, Apr. 15, 1907 (another physician), secondary growth poulticed for 2 months (another physician)	Inoperable recurrent carcinoma of lip and glands of neck, mass in neck broken down and enlarging freely.	June 22 to Aug. 12, 1907.	1 Hastened breaking down of mass in neck. 2 Temporary improvement 3 None 4 None. 5 None.	Died Sept 7, 1907.
Internal medication and ointments locally (other physicians). Removal of left inguinal glands and high amputation of penis, Dec. 10, 1906 (Bainbridge).	Enzyme treatment begun immediately after operation.	Dec. 11 1906 to Apr 28, 1907. (100 minims of "Quadruple X" trypsin, alternating with amylopsin of same strength.)	Temporary gain in weight and improvement of general condition. Otherwise negative.	Died Jun 9, 1907

Case	Name	Sex	Age	Nationality	Color	Single Married	Occupation	Private or Hospital	Referred by or in Consultation with	Diagnosis: 1 Clinical 2 Microscopic	Location of Disease	Duration of Disease Previous to Enzyme Treatment

Previous Treatment	Condition When Enzyme Treatment was Begun	Duration of Enzyme Treatment	Effect Upon. 1 Local Condition 2 General Condition 3 Fetor 4 Pain 5 Progress of the Disease	Result
Internal medication and local treatment for leucorrhea (other physicians). Uterus curetted and packed with iodoform gauze; laparotomy, disease irremovable; ovarian arteries ligated.	Extensive cancer of uterus, uterus adherent to rectum; bladder involved.	Apr. 25 to June 3, 1907	1 Temporary improvement. 2 Temporary improvement. 3 Lessened at first. 4 Lessened. 5 Rapidity of growth apparently checked (improvement probably due to tying of vessels.)	Died June 24, 1907
Antisyphilitic treatment (other physicians).	Ulcerating mass involving right half of tongue; glands of neck enlarged; buccal cavity extremely foul.	Mar. 23 to June 2, 1907	1 Buccal cavity cleaned up somewhat. 2 Temporary improvement. 3 Lessened. 4 Lessened. 5 None.	Died June 3, 1907 (hemorrhage
Treatment for constipation, later for hemorrhoids (other physicians). Refused operation, when first seen. Later (Jan. 3, 1907) consented to removal of tumor from rectum (Bainbridge).	Enzyme treatment begun immediately after operation.	Jan. 5 to May 11, 1907.	Temporary improvement in general condition otherwise negative.	Died May 19, 1907
Removal of growth on lower lip (Bagley). Removal of glands of neck (Chas. Mayo). x-ray (Bagley).	Large mass in inframaxillary region; irremovable. General condition good.	May 23 to Aug. 2, 1907. Full treatment (Bainbridge). After returning home, regime continued and 8 injections (Bagley). 12 injections (Fahey).	1 Temporary slight improvement. 2 Temporary improvement 3 No fetor present. 4 None. 5 None.	Died Oct. 27 1907.
None.	Inoperable	Apr 3 to 29, 1908. . .	Negative in all respects.	Died May 8, 1908.
None. Refused operation. Operable	Ulcerating tumor of right breast	Nov. 10, 1907, to Jan. 26, 1908.	1 Ulcer became cleaner; some contraction. 2 Improved. 3 Lessened. 4 None 5 None.	Discharged Dec. 20, 1907. Admitted to City Hosp. service of Dr. E. M. Foote. Finally consented to removal of tumor Jan. 27, 1908. Transferred to Metropolitan Hos. Backwell's Is. on account of tuberculosis of lungs. May 15 1908. Lost sight of
Removal of growth on tongue, Feb, 1906 (another hospital).	Inoperable, recurrent carcinoma	Sept. 21, 1907 to Mar. 15, 1908.	Negative in all respects.	Died Mar. 17, 1908
Removal of growth on vulva, Aug. 15, 1906; removal of inguinal glands, curettage and packing of uterus, Oct. 16, 1906 (Bainbridge).	Patient convalescent from last operation; irremovable	Nov. 5, 1906 to Jan. 13, 1907.	Hastened breaking down of growth and ulceration into femoral vessels, resulting in death from hemorrhage.	Died January 16, 1907.
Antisyphilitic treatment 3 mo., mouth cauterized (another physician). Extensive removal of diseased tissue, Nov. 15, 1906 (Bainbridge).	Mass size of marble in left submaxillary region; induration in floor of mouth.	Jan. 2 to Mar. 10, 1907.	Negative in all respects. . . .	Died Sept. 8, 1908.
Ointments for hemorrhoids; osteopathy (other physicians).	Inoperable. Growth 3 inches from anus, extending up 6 inches.	Jan. 8 to July 26, 1907.	Marked temporary improvement in general condition (probably due to regime in hospital).	Died July 27, 1907
Removal of breast, Feb., 1906. Axilla not cleared. Recurrence in axilla within 2 weeks, incised, Mar. 5, 1906 (other physicians). First portion of subclavian artery tied in order to control severe hemorrhages, Mar. 26, 1907 (Bainbridge).	Irremovable, large, sarcomatous mass filling left axilla, fixed to chest wall, involving axillary vessels; mass size of large orange over scar of old operation hemorrhage profuse.	Apr. 3 to May 15, 1907.	Ulcerating surface cleaned up by lotio pancreatis; otherwise negative.	Died June 14, 1907.
Hysterectomy, Apr. 6, 1906 (another physician). Removal of as much as possible of recurrent growth, Feb. 26, 1907 (Bainbridge).	Cauliflower-like mass involving site of hysterectomy and fornices of vagina; pelvic glands involved; general condition very poor, suffering from sepsis.	Dec. 22, 1906 to Feb. 19, 1907	1 Improved for a time. 2 Markedly improved. 3 Lessened. 4 Lessened. 5 None.	Died, June, 1907.
Primary growth removed June 2, 1906 (another hospital).	Inoperable recurrent carcinoma of uterus.	Jan. 8 to Mar. 27, 1907.	Injections caused unusual pain. After a time trypsin was not absorbed promptly and several so-called "trypsin abscesses" were formed. Material removed from these proved to be unabsorbed trypsin. Negative in all respects.	Died Mar. 29 1907
Removal of right breast and axillary glands; skin grafting, Nov. 3, 1906 (Bainbridge).	Recurrence in sternum and soft parts covering it. Irremovable.	Mar. 13, 1908 to Apr. 11, 1908.	Negative in all respects	Died during the summer, 1908.
None	Enlarged glands in neck, neck measured 15½ inches	Mar. 24 to Apr. 12, 1907.	Injections so painful patient refused to take treatment longer. Negative in all respects.	Died a few months later.
Operation refused	Ulcerated mass size of hen's egg attached to angle of lower maxilla, submaxillary and sublingual glands involved, able to open mouth only slightly. Operable.	Sept. 17 to Dec. 20, 1907	Negative in all respects	Died Dec. 22, 1907

34	A. F.	F.	43	Irish	White.	Married	Housewife.	Private.	Edward F. Duffy, Yonkers, N. Y.	1 Carcinoma. 2 Carcinoma.	Primary: Right brest. Secondary: Left breast and skin. Uterine fibroid.	6 months.
35 Test Case	M. D.	F.	50	Canadian	White.	Married	Housewife	Hospital.	Emil Brunor, N. Y. City.	1 Carcinoma. 2 Carcinoma.	Uterus, broad ligaments, bladder, rectum, and pelvic fascia.	1 year.
36	I. S.	M.	44	Russian	White.	Married	Bartender.	Hospital.		1 Ulcer of stomach, probably carcinomatous.	Stomach	8 years.
37	S. S.	F.	42	Russian	White.	Married	Housewife.	Hospital.		1 Carcinoma. 2 Carcinoma.	Primary: Right breast. Secondary: Scar of operation, chest wall, axillary and supraclavicular glands, right side; left breast.	18 months.
38	E. S.	F.	36	Hungarian.	White.	Married	Housewife.	Hospital.		1 Carcinoma. 2 Carcinoma.	Uterus and broad ligaments.	7 months.
39	S. D.	F.	38	U. S.	White.	Married	Housewife.	Private.		1 Carcinoma.	Left breast and axillary glands.	5 years.
40	P. G.	M.	66	Irish	White.	Married	Engineer.	Hospital.		1 Carcinoma. 2 Carcinoma.	Abdomen (probably mesentery and omentum) and abdominal wall.	2½ years.
41	M. M.	F.	56	Irish	White.	Single.	Housemaid	Hospital.		1 Carcinoma. 2 Cacrinoma.	Stomach	16 months.
42	F. E.	M.	42	U. S.	White.	Married	Newspaper work.	Private.	F. R. Johnson, Llewellyn Hatch.	1 Epithelioma 2 "Typical epidermoid cancer."	Tongue and glands of neck.	8 months.
43	K. M. W.	F.	45	U. S.	White.	Married	Actress.	Hospital		1 Carcinoma. 2 Carcinoma.	Left breast (1905). Right breast (1908).	4 months (right breast)
44	G. U.	M.	47	German	White.	Married	Printer.	Hospital.		1 Carcinoma. 2 Carcinoma.	Left inguinal region and rectum.	9 months.
45	L. C.	F.	40	U. S.	White.	Married	Nurse.	Hospital.		1 Carcinoma. 2 Carcinoma.	Left breast and supraclavicular glands (recurrent).	2 years (primary), 3 months (secondary).
46	N. C.	M.	62	Italian	White.	Married	Restaurant keeper.	Hospital.		1 Carcinoma. 2 Carcinoma	Rectum	About 1 year.
47	R. A. P.	F.	39	U. S.	White.	Married	Housewife.	Private.		1 Carcinoma. 2 Carcinoma.	Primary: Left breast. Secondary: Scar and supraclavicular glands.	3 years.

Previous Treatment	Condition When Enzyme Treatment Was Begun	Duration of Enzyme Treatment	Effect Upon: 1 Local Condition 2 General Condition 3 Fetor 4 Pain 5 Progress of the Disease	Result
Curettage and packing of vagina (other physicians); curettage, Dec. 3, 1907.	Irremovable. Cachexia marked tissue involved very friabl General condition poor	Dec. 21, 1907 to Jan. 24, 1908.	Negative in all respects. Disease continued to progress, involving abdominal viscera, as shown by exploratory laparotomy Feb 26, 1908.	Died Feb. 27, 1908
Right breast removed, Aug. 13, 1907 (Duffy); X-ray twice a week for 2 mo. following operation Left breast, axillary and supraclavicular glands removed, Dec. 17, 1907 (Bainbridge). X-ray every other day for several weeks (H. G. Keith, Yonkers, N. Y.).	All external evidence of cancer removed. General condition p	Dec. 27, 1907 to Mar 11 1908. Continued several weeks by Dr James T. Gordon, Yonkers, N. Y.	1 Some of the secondary nodules disappeared and others decreased in size 2 Marked improvement. 3 No fetor present. 4 Apparently controlled, certainly not increased. 5 Did not prevent metastasis or recurrence.	Died June 16, 1908
Tumor of right breast removed in 1902 (another physician). Tubes and ovaries removed, both ovarian arteries tied, Dec. 5, 1907 (Bainbridge).	Irremovable carcinoma of structures involved.	Internal medication and hypodermic injections of glycerin and water, Dec. 13 to 29, 1907. Regular enzyme treatment continued by Dr. Emil Brunor. Nov. 26, 1907 to Apr. 26, 1908.	Under control treatment steadily improvement in general condition. Began to fail as soon as the injections of trypsin and amylopsin were begun. No metastases after beginning enzyme treatment.	Died Apr 27, 1908
Appendectomy, 1900; gastro-enterostomy, 1901; plastic operation for enlarging contracted gastro-enteric orifice, 1902, medical treatment for persistent vomiting, 1907 (another hospital). Exploratory laparotomy, gastro-jejunostomy, Mar. 30, 1908 (Bainbridge).	Persistent vomiting; pain in epigastrium. Chronic gastric ulcer with peritoneal adhesions.	Feb. 27 to Mar. 26, 1908.	Negative in all respects	Died May, 1908.
Tumor in right breast removed, Sept. 1905 (another physician). Radical removal of right breast and enlarged axillary and supraclavicular glands of right side; removal of small nodule from outer portion of left breast, Nov. 12, 1906 (Bainbridge).	Irremovable involvement of chest wall.	Nov. 11, 1906 to Feb. 6, 1907.	Improvement of general condition, attributable to operation. Progress of disease not checked.	Discharged from hospital, Feb. 6, 1907. Not able to trace subsequent history.
Curettage and application of zinc chlorid, Mar. 21, 1907 (Bainbridge).	Irremovable. Suffering from sepsis, cachexia marked.	Mar. 19 to May 24, 1907.	1 Improved. 2 Less septic, less cachectic. 3 Lessened. 4 None. 5 None. Improvement doubtless due to regime rather than to the injections.	Discharged from hospital, May 24, 1907. Unable to trace subsequent history.
Pastes. Refused operation.....	Large ulcerating tumor in left breast and one in axilla; arm very much swollen; pain intense.	Apr. 28 to May 27, 1907.	Complained of pain from injections. Negative in all respects.	Discontinued treatment at patient's request, May 27, 1907. Lost sight of.
Tumor incised, Aug., 1906 (another hospital).	Tumor extending from umbilicus to symphysis pubis, hard, irregular, slightly nodular. Just below umbilicus a discharging sinus resulting from operation.	May 5 to June 3, 1907..	Slight apparent improvement in general condition at first.	Discharged from hospital by request June 3, 1907 Lost sight of.
Internal medical (other physicians). Exploratory laparotomy, Feb. 11, 1907 (Bainbridge).	General condition poor. Operation showed large, hard growth connecting stomach, pancreas and colon.	Feb. 14 to Apr. 28, 1907.	Decided improvement in general condition.	Discharged by request, improved, Apr. 29, 1907. Lost sight of.
Antispecific treatment 3 mo.; 11 caustic applications (other physicians). Extensive dissection of broken down glands in neck and involved sheaths of vessels; internal jugular vein ligated, Nov. 3, 1906, both sides of neck curetted; facial, inferior maxillary division of fifth and posterior auricular nerves cut to relieve pain, Jan. 17, 1907 (Bainbridge).	Ulcerating cancer of tongue, too far advanced to warrant removal of tongue.	Dec. 11, 1906 to Jan. 14, 1907.	Apparent temporary improvement both local and general. Autopsy showed no metastases, despite extensive involvment.	Died Jan. 20, 1907
Tumor removed from left breast, 1905; radical removal of left breast and axillary glands, Sept., 1907 (other hospitals). Radical removal of right breast and axillary glands, Apr. 2, 1908 (New York Skin and Cancer Hospital).	Enzyme treatment begun two weeks after last operation, to prevent metastasis.	Apr 15 to 24, 1908. Large doses.	Negative in all respects.	Discharged by request, Apr. 25, 1908. Lost sight of.
Operation for fissure of rectum, June 6, 1907, exploratory laparatomy, left inguinal colostomy, July 15, 1907 (another hospital).	Tumor in rectum, 3½ inches from anus; left inguinal glands enlarged. Inoperable.	Jan. 10 to 31, 1908...	Temporary improvement in general condition. Otherwise negative	Discharged Jan. 31, 1908, steadily growing worse. Died later
Left breast and supraclavicular glands removed, July 16, 1906 (another hospital).	Recurrence in scar of breast amputation; arm and hand greatly swollen and very painful Operation refused.	Mar. 1 to May 7, 1908	Negative in all respects. Treatment painful when large injections were used.	Refused further treatment. Discharged Mar. 8, 1908. Lost sight of.
Hemorrhoids removed by cautery, Sept. 1906 (another physician). Rectum dilated, Jan. 19, 1907 (Bainbridge). Further operation refused.	Nodular masses for a distance of 3 inches in rectum; annular mass extending 2 inches further Pain constipation, bloody stools.	Nov. 18, 1906 to Apr. 16, 1907.	1 Discharge from rectum freer, obstruction not so marked. 2 Temporarily improved. 3 Lessened. 4 Lessened. 5 None.	Died Mar., 1908.
Removal of breast, Feb., 1906 (another hospital). Refused further operation.	Irremovable. Considerable pain General condition fair.	Feb. 19, 1907 to Apr 27, 1907.	1 Distinct improvement. Some nodules apparently disappeared and others decreased in size and became softer. 2 Gained 17 lb. in less than 1 mo. 3 Lessened. 4 Lessened for a time. 5 Seemingly retarded.	Discontinued treatment voluntarily Apr. 27, 1907. Died several months later.

Previous Treatment	Condition When Enzyme Treatment Was Begun	Duration of Enzyme Treatment	Effect Upon 1 Local Condition 2 General Condition 3 Fetor 4 Pain 5 Progress of the Disease	Result
Removal of growth from tongue, one week later, removal of a larger section from tongue, and supraclavicular glands, Aug., 1907 (another hospital).	Large mass behind ramus of left jaw, extending to symphysis; ulcer on right side of tongue; right side of neck swollen. Irremovable.	Nov. 1 to 9, 1907	Pain seemingly increased. Otherwise negative	Discharged by request Nov. 9, 1907. Died later.
None	Large parenchymatous goitre	Mar. 1 to Apr. 30, 1907. Large doses of trypsin and amylopsin.	Painful indurated area at site of injection. No effect upon the goitre, which was removed May 24, 1907 (Bainbridge)	Uneventful recovery from operation; perfectly well May 17, 1907.
None	Nodular mass size of walnut over nipple of right breast; slight ulceration, no discharge; axillary glands enlarged. Operable, operation refused.	Dec. 7, 1907 to Feb. 27, 1908, in hospital, and irregularly for 8 mo. after returning home (Cladek).	Gained 10 lb. in weight while in hospital, appetite improved. Progress of the disease seemingly retarded but not stopped.	Discharged Feb. 27, 1908. May 12, 1909, patient able to do light housework. Disease slowly progressing.
X-ray, a few times, radium, 2 months (other physicians). No operation.	Ulcerating growth involved entire auricle and contiguous post-auricular area.	Feb. 8 to May 12, 1908.	1 Ulcerating surface cleaned up. 2 None. 3 None. 4 Lessened for a time 5 None	Insisted upon discontinuance of injections because of pain. Still under observation. Disease gradually progressing.
Tumor incised and packed, 3 mos. after its appearance (another hospital). Tumor removed by plaster a short time after this (another physician). No return until Mar., 1907, when a blow was received on the temple. Soft tissues involved, portions of the malar, frontal and superior maxilla removed, the right eyeball enucleated and the orbital fossa cleared out, Dec. 12, 1907 (Bainbridge)	Patient recovering from operation when treatment was begun. Irremovable in part.	Dec. 21, 1907 to Jan. 16, 1908. No injections given; all other parts of treatment as usual.	Seemed to gain for a time. Injections painful. Grew progressively worse	Died Apr. 10, 1908.
Growth on foot removed, enlarged inguinal glands excised, and femoral abscess evacuated Mar. 25, 1908 (Bainbridge).	Suffering from absorption of toxic products; general condition very poor.	Apr. 6 to 19, 1908	Negative in all respects.	Discharged by request May 2, 1908. Died a few days later.
Tumor in breast opened as an abscess, about 2 years ago (another physician); removal of left breast, about 2 months later (another hospital). Axillar and supraclavicular glands and mass in right breast not removed.	Numerous small masses over chest wall; large discharging mass over site of left breast; glands in neck and axillæ markedly enlarged. Inoperable except for paracentesis for removal of fluid from chest cavity.	Nov. 6 to Dec. 26, 1907	Reaction very severe; no beneficial effects; treatment abandoned because of patient's weakened condition.	Died Jan. 2[illegible] 1908.
None	Carcinomatous masses extending from base of tongue to hyoid bone involving epiglottis and larynx, interfering with deglutition. Inoperable.	Jan. 3 to Mar. 8, 1908	Negative in all respects.	Died Apr. 8, 1908.
Removal of primary growth in 1903 (another hospital).	Irremovable ulcerating growth involving the tissues named.	Jan. 9, to Sept. 18, 1908. (Injections 2 months, internal treatment 9 months).	1 Ulcerated surface on cheek decreased in size, floor cleaner and healthier. 2 Improved temporarily. 3 Lessened. 4 Lessened. 5 Growth seemed to be checked to some extent at first, later disease progressed rapidly.	Removed to Bellevue Insane Pavilion Sept. 18, 1908. Died shortly after.
Hospital treatment 4 months. Operation refused.	Characteristic symptoms of cancer of stomach.	Jan. 2 to May 9, 1907. .	Improved, probably because of the 4 months' hospital régime and treatment	Discharged by request May 9, 1907.
Removal of left breast (1900) (another hospital). Removal of foci in chest wall, part of sternum and ribs over heart, extensive operations (four) in 1906 and 1907 (Bainbridge).	No disease apparent.	Dec. 12, 1906 to May 10, 1907. (To prevent recurrence)	General condition improved. Considerable local pain not influenced.	Discharged May 11, 1907. Received electrical treatment for 3 mos. after leaving hospital. No recurrence at present
Treated for cystitis (another physician).	Hemorrhages from bladder; incontinence of urine.	June 1 to July 15, 1907.	Negative in all respects.	Died Aug. 14, 1907
Panhysterectomy, Nov. 2, 1905 (Bainbridge)	Inoperable.	Feb. 4 to Aug. 17, 1907. Jan. 16 to Apr. 7, 1908	General condition much better for a number of months. Treatment seemed definitely to prolong life. Disease steadily progressed.	Died Apr. 18, 1908
Halsted operation for removal of left breast, June, 1906 (another hospital). Axilla cleared, June 20, 1907 (Bainbridge). Further operation refused.	Recurrence in scar of breast amputation.	Dec. 10, 1907 to Jan. 10, 1908. Further treatment refused	Negative in all respects.	Died May 30, 1908
Vaginal hysterectomy, Oct., 1906 (another hospital)	Mass in pelvis size of fist; ulcerated surface at vault of vagina. Anemic, otherwise general condition good. Irremovable	3 weeks, small doses (Dunn). Jan. 15 to Feb. 12, 1907 (Bainbridge). Full doses	Only effect, increase in discharge from ulcerating surface in vault of vagina	Died Apr. 4, 1907
Palliative (other physicians). .	Inoperable.	Feb. to May, small doses. May 9 to 24, 1907. Refused further treatment.	Negative except that it seemed to relieve pain for a time	Died June 3, 1907
None	Mass in epigastric region, hemorrhages from stomach.	Jan. 23 to Mar. 11, 1907	Negative except for improvement in digestion	Died Apr. 24, 1907
Surface of tumor curetted (another physician)	Large inoperable uterine cancer. Patient confined to bed	Jan. 18 to Feb. 15, 1907	Improvement in general condition for a few days, discharge increased. Otherwise negative	Died Feb. [illegible], 1907

Previous Treatment	Condition When Enzyme Treatment Was Begun	Duration of Enzyme Treatment	Effect Upon 1 Local Condition 2 General Condition 3 Fetor 4 Pain 5 Progress of the Disease	Result
X-ray, bovinine (other physicians). No operation.	Inoperable. General condition fair	Dec. 28, 1906 to Mar 27, 1907	Negative in all respects.	Died later.
Removal of tumor in left breast (another physician).	Small injections of trypsin (10) and amylopsin (2) during Oct 1907 (Green) Dec 26, 1907 to Feb. 21, 1908.	Oct 5, 1906 to Feb. 21, 1907 Small injections at first, gradually increased.	Tumor in right breast disappeared, but returned again. Disease steadily progressed	Died Feb. 21, 1907
Hysterectomy, 1906 (another hospital).	Recurrent tumor in pelvis, very painful; general toxemia from failure of emunctory organs to functionate.	Apr 17 to June 16, 1907	Gained 5 lb. in weight; much stronger, less pain at first. Progress of disease not influenced	Died June 16, 1907
Breast lanced three times (another physician) Breast and axillary glands removed, Aug., 1906 (Faison). X-ray four times in Feb., 1907.	Ulcerating sarcoma; profuse hemorrhage; weak, emaciated	Mar. 2 to Apr. 2, 1907.	Negative in all respects.	Died Apr 3, 1907
Complete removal of breast and glands of axilla, Apr., 1903, X-ray 2 years thereafter (Clarke). Radium a few days (another physician). Removal of recurrences, Nov. 7, 1907 (Bainbridge). Small recurrent nodule removed under cocain anesthesia, Jan. 9, 1909 (Bainbridge).	Small discharging sinus in axilla recurrent nodules in skin; general condition good; contraction of scar and edema of arm.	Nov 25, 1907 to Feb. 26, 1908. Given in the hope of preventing metastasis. June 2 to July 14, 1908.	Did not prevent recurrence Whether it influenced extent of recurrence cannot be determined.	Free from apparent disease, May 12, 1909.
None.....	Liver very much enlarged Progressive loss of appetite, strength and weight; nauseated all the time.	Dec. 22 to 27. Refused further treatment.	Negative Patient complained of the pain of injections.	Died a few weeks later.
Iodine at intervals, palliative treatment. X-ray three times a week for nine weeks, 1906. Relieved pressure by exploratory operation, Dec. 6, 1906 (Bainbridge).	Tumor pressing upon superior laryngeal nerve; paralysis of left side of face. Difficult deglutition	Dec. 9, 1906 to May 6, 1907	1 Growth in neck decreased in size 2 Improved Able to swallow more easily; facial paralysis less marked. 3 None present. 4 Lessened. 5 Retarded; life prolonged.	Died May 15, 1907
Removal of growth on ankle, June 22, 1907. Refused to allow removal of inguinal glands, until Mar. 10, 1908.	Recurrence in abdominal viscera General condition fair	Dec 1, 1907 to Feb. 14, 1908.	Negative in all respects. Did not prevent metastasis, as autopsy showed metastases in all the abdominal viscera	Died Mar. 12, 1908
Cauterization (alum stick); treated for tuberculosis (other physicians) Removal of tongue and glands of neck Aug. 1907 (Bainbridge)	Inoperable recurrence in floor of mouth and neck. Thin and cachectic. Pain severe.	Feb. 27 to May. 8, 1908.	Negative in all respects	Died May 10, 1908
General tonic treatment; uterus cauterized (another hospital).	Inoperable carcinoma of uterus and bladder Constipation, frequent urination, severe pain	From Oct to Dec 1907 received 10 injections trypsin and 2 amylopsin, then liquid glycerin trypsin (Green), Holadin, oxgall and dietary regime from Dec. 26, 1907, to time of death, some six weeks later.	Distinct evidence of depression after small injections of trypsin Negative except for temporary general improvement.	Died some weeks later (early in 1908)
Antisyphilitic treatment for a number of months; X-ray three times (other physicians). Removal of tongue and glands of neck, Mar. 1907 (Bainbridge)	Recurrence in neck, throat and back Septic looking, emaciated, exceedingly nervous.	Mar. 23 to Sept 26, 1907.	Pain seemed to be increased by treatment. No favorable effect Disease steadily progressed.	Died May 3, 1908.
Hysterectomy, Apr., 1906 (another physician).	Extensive involvement of pelvis. General condition very poor.	Nov. 7 to 19, 1906 ...	Negative in all respects.	Died Nov. 21, 1906.
Complete amputation of breast Apr. 8, 1907 (another hospital).	Inoperable recurrence in scar of operation, nodules in surrounding skin; supra- and infraclavicular glands. Arm greatly swollen	July 1, 1907 to Nov 2, 1908.	Improved under regime for a time.	Died some months later.
Hysterectomy, Aug. 23, 1905 (another hospital).	Neuralgic pains in left hip and leg Small ulcerated area in vagina Operation refused.	Jan. 13 to Apr. 12, 1907	Negative. Disease steadily progressed	Died Apr. 3 1908.
Uterus curetted; ovarian and uterine arteries, both sides, ligated, Apr. 18, 1908.	Extensive involvement of uterus, broad ligaments and bladder found upon exploration Irremovable.	May 6 to Nov. 2, 1908.	Temporary check to growth, as indicated by symptoms, probably due to ligation of vessels	Discharged, improved June 4 1908 Disease slowly progressing but patient able to do light housework
Ointment (family physician). Refused operation.	Hard, eroded tumor in breast, nipple retracted Progressive loss of flesh and strength	Apr 1 to July 1, 1908..	Lost 15 lb in weight while on the treatment. Negative.	Died July 7, 1908.
Primary growth, with free margin of healthy tissue, excised, July 21, 1906 (hospital).	Extensive involvement of buccal mucous membrane; foul discharge, intense pain.	Apr 3 to Sept 19 1908 Refused further treatment.	Negative in all respects	Died in few weeks later
Breast amputated, July, 1906; recurrence in scar excised, Feb. 10, 1908 (another hospital)	Induration of edges of wound from last operation, which never healed Eroded area 3 inches long in axilla, with protruding ulcerating mass.	March 25 to June 1, 1908	1 Wound cleaned up by Lotio Pancreatis Discharge increased 2 Loss of weight; increased cachexia. 3 Lessened 4 None. 5 None	Died Dec. 1, 1908.

Previous Treatment	Condition When Enzyme Treatment Was Begun	Duration of Enzyme Treatment	Effect Upon: 1 Local Condition 2 General Condition 3 Fetor 4 Pain 5 Progress of the Disease.	Result
Removal of primary growth, Jan., 1906 (another physician). Curetted ulcerating surface, June 14, 1906. (Bainbridge.)	Ulcerating mass in neck. Fe... mastoid process. Very fetid.	Oct. 24, 1906, to March 19, 1907.	Negative in all respects.	Died Mar. 2[illegible] 1907.
Potassium Iodid; cauterization (Fewsmith). Amputation of tongue, April 11, 1908. Removal of cystic tumor, supra-clavicular region, May 4, 1908. (Bainbridge.)	Treatment begun after second operation.	May 20 to June 12, 1908.	Negative in all respects.	Died later.
No operative interference.	Glands of neck broken down. Ulceration extending to tongue and buccal mucous membrane. Inoperable.	Feb. 10 to Oct. 4, 1908. Discontinued at patient's request.	Negative in all respects.	Alive Jan. 1909. In fairly good condition.
None.	Irremovable, ulcerating tumor involving uterus and vagina. Loss of 20 pounds in weight in [illegible] months, fetid bloody vaginal discharge.	April 10 to June 27, 1908. No injections.	Lotio Pancreatis caused slight temporary improvement in fetid discharge. Otherwise negative.	Discharged by request June 27, 1908. Died later.
None. Operation refused.	Large mass in breast, nipple retracted, axillary glands enlarged. Operable.	June 1 to Nov. 2, 1908.	Negative in all respects. Development of disease very slow but progressive.	Alive April 26, 1909. About the same as when treatment was discontinued.
None. Operation refused.	Hard mass size of orange in breast, glands of neck carcinomatous.	March 13 to Oct. 2, 1908. Discontinued at patient's request.	Negative in all respects.	Lost sight of.
None. Operation refused.	Hard mass size of orange in neck.	May 1 to June 15, 1908. Discontinued at patient's request.	Negative in all respects.	Discharged June 20, 1909. Died later.
None.	Inoperable. Cachectic, weak, emaciated, vaginal discharge, pain in back.	Jan. 13 to April 11, 1908, injections of sterile water, and the internal treatment. April 11 to May 1, 1908, full Trypsin treatment.	Did as well upon the injections of sterile water as upon the trypsin and amylopsin injections. Negative.	Died July 1908.
Salves, washes, X-ray, at intervals for several years (other physicians). Removal of involved soft parts and resection of lower maxilla, 1908 (Bainbridge). April 18, several subsequent curettments of granulating surface and removal of necrotic tissue (hospital). Removal of diseased soft parts and resection of 2 inches of central portion of lower maxilla; plastic operation, Dec. 19, 1908. (Bainbridge.) Removal of necrotic bone, Jan. 19, 1909. (Bainbridge.)	Treatment begun after second operation (June 3, 1908 for removal of necrosed bone.	Sterile water injections and regime, June 3 to 9, 1908. Dietary regime, with occasional resort to the internal medication, continued during stay in hospital.	General condition improved, probably due to regime. Disease progressed, despite frequent operations.	Discharged improved, Feb. 9, 1908.
Breast removed, June, 1906 (another hospital). Recurrence in chest wall excised, outer surface of ribs and costal cartilages curetted, April 13, 1908; supraclavicular region explored and nodules encroaching upon carotid and subclavian dissected out, May 18, 1908. (Bainbridge.)	Treatment begun after second operation.	June 18 to 30, 1908. Discontinued at patient's request.	Injections very painful. Negative.	Discharged July 1908, improved from operation. Lost sight of.
Anterior rectal wall and diseased portion of vagina exsected, June 25, 1907; both ovaries and tubes removed, both ovarian arteries ligated and both broad ligaments constricted by ligature near pelvic wall, Feb. 7, 1908. Further operative procedure impossible. (Bainbridge.)	Treatment begun shortly after second operation; patient in better condition than before.	Feb. 24 to July 31, 1908. (Irregularly.)	Negative in all respects.	Died Aug. 17, 1908.
Hysterectomy, Dec., 1906 (another hospital).	Mass in groin attached to [illegible].	Feb. 20 to April 14, 1908.	Negative in all respects.	Died June [illegible], 1908.
Double oophorectomy, ligation of ovarian and uterine arteries, April 27, 1908; removal of masses from vaginal wall and cervix, May 25, 1908. (Bainbridge.)	Irremovable, condition [illegible] as result of operation.	June 8 to July 31, 1908, regular treatment. July 31 to Aug. 30, 1908, trypsin per rectum.	Negative in all respects.	Died Sept. [illegible], 1908.
Primary growth removed, Oct., 1906 (another hospital). Removal of as much as possible of diseased tissue, April 11, 1908. (Bainbridge.) Excision of submental, submaxillary and superior carotid triangles; ligation of left external carotid, sublingual, superior thyroid, ascending pharyngeal, facial, and posterior occipital arteries, April 11, 1908, subsequent injection of right carotid with paraffin. (Bainbridge.)	Treatment begun immediately after ligation of arteries. Irremovable.	April 13 to July 23, 1908.	Negative in all respects.	Discharged by request, July 24, 1908.
Tracheotomy (another physician).	Dyspnea, general condition [illegible].	Dec. 19, 1907, to June 13, 1908. Large doses [illegible].	Improved somewhat for a time.	Died July 2, 1908.
None. Refused operation.....	Tumor in breast hard and [illegible], involving entire gland.	July 20 to Dec. 11, 1908.	Malaise, insomnia and pain decreased definitely. Decreased by [illegible].	Discharged Dec. 11, 1908. Lost sight of.
Medicinal and dietetic. Refused operation.	Anemic, cachectic, [illegible], losing weight. Tumor [illegible] hen's egg in body of [illegible].	May 1 to July 8, 1908.	Tumor decreased in size, pain alleviated, gained 20 pounds in weight, returned to work.	Died a few months later from pneumonia.

treatment instituted July 1, 1907, and continued until April 4, 1908. During this time the patient received 70 injections of trypsin and 40 of amylopsin. The internal treatment was given throughout the entire time the patient was under observation. Three abscesses formed at the sites of injections, apparently from nonabsorption of the material. During April and May there was a gradual increase in the size of the left arm, which slowly decreased during June.

In September, at the patient's request, the trypsin injections were again instituted. Twelve injections of trypsin and four of amylopsin were given during the second course of treatment. At the time of beginning the blood examinations in April, 1908, the patient had been on amylopsin for over a month. During April there was a relative lymphocytosis (increase of small mononuclears) of 9 to 20 per cent. above the normal average, the total number of small mononuclears varying between 3,420 and 6,195 per cubic millimeter. This was in the month preceding the marked evidences of renewed growth objectively present in May. The relative increase of these small mononuclears in May was 8 to 11 per cent. above the normal average. From July 15 to September 1, but one blood count was made. During the second return to trypsin injections the per cent. of small mononuclears was not relatively increased as constantly or as high as in the preceding months, the total numbers averaging between 1,160 and 3,325 per cubic millimeter. The eosinophiles during April and May varied between 155 and 245 per cubic millimeter; after discontinuing all injections between 85 and 113 per cubic millimeter, during September and October they increased to 300 per cubic millimeter.

Case 91.—Ephithelioma of Chin and Lower Jaw. Control case. Sterile water injections were begun the last of May, shortly after the second operation. The blood counts showed a marked relative lymphocytosis, there being from 44 to 49 per cent. of small mononuclears in a total white cell count varying between 7,500 and 8,500. June 11 they dropped to 24 per cent., rising relatively to 48 per cent. on June 16, two days before the patient's third operation. The eosinophiles increased from 37 per cubic millimeter June 4 to 552 per cubic millimeter June 16—to be expected from involvement of bone. A white cell count was not again made until July 25, when there was a relative lymphocytosis of 35.8 per cent. of large mononuclears and transitionals out of a total count of 6,000 white blood cells per cubic millimeter. The increase of small and large mononuclears continued until the fourth operation, August 25, 1908. Two weeks later the counts were relatively 26.2 per cent. and 8.8 per cent., the polynuclears being 63.8 per cent. September 23 the small mononuclears were again relatively high, 43.8 per cent., while the large mononuclears were nearer normal, 7.8 per cent. The small mononuclears varied the following five weeks between 38 per cent. and 43.4 per cent. During these five weeks the total white cell count varied between 9,500 and 11,000 per cubic millimeter. The eosinophiles increased from 105 to 315 per cubic millimeter. Injections of sterile water were now discontinued; the internal administration of holadin was also stopped. The patient began to gain in weight at the rate of a pound and three-quarters a week. The hemoglobin improved slightly and the number of red cells increased.

IVY POISONING.

By ADDISON W. BAIRD, M.D.,

NEW YORK.

At this season of the year there occur many cases of ivy poisoning, from the plant *Rhus toxicodendron*. The symptoms of redness, swelling, and heat, with formation of vesicles of bullæ, and sensations of itching and burning, are well known. The trouble is of all degrees, from a mild erythema to severe inflammation accompanied by constitutional disturbance. The disease is ordinarily self-limited, so that there are many apparent cures. Applications of lime-water, bicarbonate of sodium solution, lead wash, or grindelia robusta, and decoction of sweet fern, locally and internally, are all considered good and modify the discomfort in many cases.

In the *Journal of Biological Chemistry*, Vol. II, No. 6, 1907, S. F. Acree and W. A. Syme relate the results of an exhaustive study of rhus poisoning in a paper entitled "The Composition of Toxicodendrol." They found that the poisonous principle was neutralized by permanganate of potassium, used preferably in warm 2 to 4 per cent watery solution.

From my own observation I have formulated the following treatment:

1. No scratching.
2. No ointments in the acute stage.
3. No bandages, for these tend to spread the poison to the adjacent surface. If any protector is necessary, let it be a loosely applied dressing of absorbent cotton, kept moist at all times and changed at short intervals.
4. Frequent and copious washings with lukewarm water and an unirritating soap. This dissolves and removes the poisonous serum which is exuded from the vesicles, and prevents its spread to the surrounding skin. Alcohol is a solvent of the poisonous principle, but the use of it tends to spread the trouble. In handling the inflamed surface it is best to wear rubber gloves.
5. After the parts are washed, apply warm solution of 2 to 4 per cent of permanganate of potassium. This completely neutralizes any poison with which it comes in contact. The strength of the solution and how often it is applied is a matter of judgment with the physician.
6. After the acute stage is past, when the disorder is considerably abated and a condition of eczema exists, the use of water may be objectionable and soothing ointments are permissible.

Permanganate of potassium stains the skin, but this is a small price to pay for the relief it affords. Hence it is hardly worth while to try to remove the discoloration by oxalic acid or other means.

239 West Seventieth Street.

Ulcerative Stomatitis.—M. H. Grenet says that stomatitis is not truly membranous, since the supposed membrane is composed only of débris of the mucous membrane. It occurs especially when the teeth are erupting, under defective hygienic conditions. It is emphatically contagious, directly and indirectly. It may develop spontaneously in an infant who has not been exposed to infection. The cause is generally spirilli and fusiform bacilli associated with other microorganisms. The characteristic is necrosis of the mucous membrane. The breath is exceedingly fetid. Ulcerations may occur at any point of the lining of the mouth. The submaxillary glands are engorged, there is salivation, and buccal pain. It may be very chronic in course. Complications are rare. The use of chlorate of potash is almost a specific for the disease.—*Gazette des Hôpitaux.*

RADIOACTIVITY AND CARCINOMA.

ALTHOUGH it has long been known that undue exposure of the integument to the *x*-rays may result in carcinoma, and also that exposure of a superficial cancer to the action of the *x*-rays and of radium may cause the disappearance of the neoplasm, it is only recently that a serious effort has been made to determine the relation of radioactivity to malignant growths. We should say, rather, that it is only recently that the results of such a study have been published, for Lazarus-Barlow, who has now given the world an account of his investigations, has been engaged in the work a long time and has conducted it in a most painstaking and accurate way. An interesting account of these prolonged researches was given by him in the Croonian Lectures delivered before the Royal College of Physicians of London in June, and published in *The Lancet* of June 26, 1909.

The investigation was prompted by the undoubted fact that workers in *x*-rays are liable to suffer from carcinoma of the hand, and with this fact in mind Lazarus-Barlow studied the radioactive properties of certain substances which are supposed to be causative of cancerous growths, such as soot, paraffin, tar, gallstones (cholesterin), clay pipes, etc., the idea being that possibly radioactivity might be an etiological factor in many or all cases of carcinoma. The numerous experiments elaborately detailed in these lectures cannot possibly be epitomized in a few paragraphs, though they are of great interest and worthy of careful study, and space will permit only of comment on certain facts in connection with them. He studied the radioactivity not only of these supposed causative factors in carcinoma, but also of certain animal tissues and organs, which are the frequent sites of cancerous growths, and of the neoplasms themselves. He tested first the so-called scotographic power of these substances and tissues, that is the power possessed by them of affecting a photographic plate in the dark, admittedly only one of the characteristics of true radioactive substances. Some of them had this power and some had not, and some of those that did have it also behaved in certain other respects like the radioactive materials of the physicists, but in no single instance did they respond to all recognized criteria. Some animal extracts displayed powers resembling those of radioactive substances and to a certain extent influenced the rate of development of animal cells, and the lecturer thought it not improbable, or at least not impossible, that the laws of radioactivity as now held might require some modification when adopted into biology, owing perhaps to the presence of the protein molecule, as in the case of osmosis. Some years ago he showed that a minute trace of protein profoundly modifies the rate of osmosis, and in these lectures he has apparently shown a similar modification in reference to photographic, or scotographic, and electroscopic results.

Some interesting points were brought out as to the respective liability to cancer of men and women and that of different tissues and organs, as disclosed by the statistics of the Middlesex Hospital. All groups show a rising liability with increasing age, but this does not continue to end of life, except in the case of cancer of the lip. In every other instance a maximum is reached, after which the liability to cancer diminishes more or less suddenly. This maximum of one organ does not occur at the same age as that of another, nor do the ascents and descents correspond in height or rapidity in all cases. There is a great contrast between cancer of the lip and that of the uterus which may depend upon difference in the cause or in the tissue. Cancer of the breast, coming as it usually does after more or less inflammatory reaction, may be in line with carcinoma in old cicatrices and ulcers. In the alimentary canal the liability is much greater in men, and further, it reaches the maximum ten years earlier and persists five years longer than in women. This, however, can hardly be due to any difference in the tissues of these parts in the two sexes. There is a striking difference between the liability of the lip and that of the tongue and other parts of the mouth, in spite of similarity of tissues and of the conditions to which they are subject. On the assumption that the pipe is related to the disease in the lip and the teeth to that in the tongue, the liability and the time limits in the two situations are readily explicable. If this means chronic irritation, as commonly expressed, Lazarus-Barlow says the term is meaningless or only indicates some common factor of a great variety of conditions, and he asks if it is not possible that this factor may be radioactivity. If such were the case, the lecturer maintained, it would fall in line with many facts recently made known and at the same time would not be opposed to some other widely held beliefs, such, for example, as the existence of cancer houses, which could be accounted for by the presence of some radioactive substance in the building material or even in the soil upon which such houses were erected. Nor did it necessarily conflict with Cohnheim's theory of embryonic rests or with Virchow's theory of mechanical irritation or with Adami's theory of habit of growth, since radioactivity in the causative agent or in the tissues might be the underlying force in each. Even the microbic theory might be reconciled with this idea, for it is supposable that the assumed bacterial or protozoan agent in such case might be radioactive.

We must confess that these researches of Laz-

arus-Barlow, interesting and novel as they are, do not seem at first sight to promise much in the way of a solution of the teazing cancer problem. The clay pipes, tar, and paraffin, among other substances, gave no sign of possessing any radioactive power, not even scotographic power, which even wood possesses in a degree, yet the clay pipe especially he believes to be a potent factor in the production of cancer of the lip. The theory of chronic irritation, which, as we have seen above, he characterizes as meaningless, has more meaning than that of radioactivity in the case of the clay pipe, a substance which has no trace of radioactivity. Nevertheless this work, inconclusive as it is in its results, is deserving of careful study and extension. Many of the facts brought out in the course of the investigation are striking and the light they throw on the problem, though revealing little as yet, may show the way to future discoveries of great and far-reaching importance. Further investigation along this line may indeed explain away the discrepancies now forbidding an acceptance of the theory, but even should they fail to do so, work of this kind is never fruitless and it may prove to have an important bearing on other biological problems, even if it does not explain the origin of cancer.

THE USE AND ABUSE OF HIGH FREQUENCY CURRENTS.

Electric currents at extremely powerful pressure, known as high-frequency currents, a few years ago were lauded to the skies as a remedy, if not a cure, for a vast number of complaints. Many members of the medical profession, itself, not only highly recommended this form of treatment, but practised it upon their patients. There were those who, but a comparatively short time ago, held that high-frequency currents were by way of being a sort of universal panacea, which, moreover, required little technical knowledge to apply; the result being that numerous physicians who knew scarcely anything of the subject installed in their offices high-frequency apparatus, and were surprised and chagrined when they found that cures did not come in the way they had anticipated. The treatment lent itself so easily to charlatanism that it was exploited by individuals not of the medical profession, and sometimes, we fear, by physicians themselves. The temptation to abuse high-frequency treatment is strong. The apparatus is impressive in a high degree to the eye of the layman, and especially it may be said to the lay woman. It is noisy with a businesslike, somewhat scientific kind of noise, the violet brush discharges and sparks are fearfully attractive, and the *tout ensemble* is particularly well calculated to impose upon ignorance.

As a consequence of the abuse of these currents, high-frequency treatment has come, to some extent, to be regarded with disfavor by specialists and physicians in this and other countries. At the same time, there is no doubt that D'Arsonval obtained very successful results when he first applied these remedial measures to the human subject some years ago, and it is probable, indeed more or less certain, that most of the secret of success in applying high-frequency currents is that one should be an expert in their manipulation, and should also thoroughly understand the various effects of the currents on the system. The physician who makes use of these methods in the treatment of disease must be conversant with his subject from all points of view.

In the *Lancet* of July 3 is a paper dealing with the matter, read recently before the Brighton and Sussex Medico-Chirurgical Society by Dr. F. C. Bailey, medical officer in charge of the electrical department of the Sussex County Hospital. This paper goes to show that the maligned high-frequency currents have great possibilities, but that these possibilities are, of course, limited, that the treatment is not by any means a "cure-all," and that to attain the greatest measure of success the methods must be intelligently applied by a person who is endowed with scientific and technical knowledge. The peculiarity of the high-frequency current lies in its extraordinarily rapid alternation, changing its direction something like a million times a second. It is obvious that a current changing with such rapidity, when sent through the human body, is of too brief duration to cause pain, or to burn or to make the muscles jump, as an ordinary current, but it has an action on the tissues which has been named microscopic massage. According to Dr. Bailey these very powerful currents produce four separate effects on the human system, according to their mode of application. These effects seem to be a raising or lowering of the tone of the heart or blood-vessels, a third kind of application is said to be indicated in the treatment of inflammations, while a fourth will stimulate the general activity of the tissues. Therefore it is asserted that if the particular effect required in the individual case be considered, high-frequency currents can be made use of with good results, always bearing in mind that they have their limitations.

All researches into the question show indubitably that the technique of high-frequency treatment cannot be mastered without the gaining of considerable experience in the manipulation of the apparatus; and, naturally, if the apparatus be not worked properly and applied with due discrimination, good results will not ensue. Undoubtedly in the past, the currents have been applied indiscriminately, and to this fact is doubtless due the disfavor into which the treatment has fallen.

Dermatitis Pediculoides Ventricosus.

For the past eight years there have occurred, in and about Philadelphia, cases of what seemed to be a new, and certainly was a decidedly puzzling, form of skin disease. The condition appeared in epidemic form, prevalent in the summer months, the small epidemics being localized to certain districts and even to particular houses. The eruption made its first appearance in a form resembling simple urticaria, in the middle of the wheals, however, soon appearing minute vesicles, these later becoming pustular. The onset of the attacks was sudden, and the duration several weeks, during which time the itching was so intense that the patients

often were obliged to abandon their occupations. The etiology of the condition was quite obscure, until recently when an outbreak among the sailors of a yacht in the harbor of Philadelphia called the attention of Goldberger, of the U. S. Public Health and Marine Hospital Service to it. He started an investigation with Schamberg, of Philadelphia, which has recently been published in the Public Health Reports, Vol. XXIV, No. 28. In all, nearly one hundred and twenty-five cases were investigated, these coming from the crews of five boats and the inmates of twenty dwelling houses. The first point to be learned, common to all the cases, was the history of recent handling or sleeping on new straw mattresses. Further investigation proved that all of these mattresses had been bought from four dealers in Philadelphia, who obtained their straw from a common source in New Jersey. Volunteers who exposed their bare arms between two of these mattresses, or slept upon them, promptly developed the disease. Some of the straw was then sifted and the dust collected in Petri dishes. One portion was placed in the axilla of a volunteer, and in sixteen hours caused the characteristic eruption. Another portion, after exposure to chloroform, when placed in the opposite axilla appeared to be quite innocuous. On careful search of the dust minute mites were discovered, five of which were obtained and, when placed on the skin under a watch crystal, produced five typical lesions of the disease. The mite was diagnosed at the U. S. Bureau of Entomology as being very close to or identical with *Pediculoides ventricosus*. As proper treatment of the infected mattresses with sulphur, steam, or formaldehyde in a vacuum chamber will kill the mite, the prophylaxis against this disease is now comparatively a simple matter.

The Much-Holzmann Psycho-Reaction.

Attention was called recently to a new blood reaction described by Much and Holzmann, which these authors considered to be specific for dementia præcox and manic depressive insanity, the reaction consisting in the property of the blood serum of such patients to prevent the hemolytic action of cobra venom upon normal blood corpuscles. At the time it was stated that the report of the authors did not seem to be quite convincing, and that before it could be accepted as a specific for these diseases it would require confirmation by less enthusiastic observers. As was to be expected on the appearance of a new discovery of such importance, others at once attempted to confirm or refute the specificity of the new test, and two reports have already appeared upon the subject. One of these, by A. H. Hüber and H. Selter, of the Hygienic Institute at Bonn, was published in the *Deutsche medizinische Wochenschrift* for July 8, 1909. The authors followed the Much-Holzmann technique in eighty-two cases. Their results differed strikingly from those of the authors of the test. Of twenty-seven cases of manic depressive insanity only twelve gave a positive reaction, while eight were doubtful, and seven negative; of twenty-four of dementia præcox, ten were positive, eight doubtful, and seven negative; while of thirty-one controls, comprising various forms of psychic and nervous ailments not belonging to the two classes of psychoses for which the test was considered specific, twenty-two reacted positively, four negatively, and four doubtfully. From these figures it will be seen that the reaction was positive in less than fifty per cent. of the cases for which it was proposed, whereas it occurred in over two-thirds of the cases in which the diseases in question were not present. The second report on the subject is by Felix Bauer, in the *Münchener medizinische Wochenschrift* for July 6, 1909. This author, basing his studies on some previous findings of his own as to the properties of the blood in the umbilical cord of new-born infants, showed that of seventeen specimens of the serum of such blood, fourteen gave positive Much-Holzmann reactions, while the other three were suggestive. If these two series of investigations were properly carried out, it would appear not only that this new reaction is not in the least specific for manic depressive insanity and dementia præcox, but that the very title of "psycho-reaction" is itself a misnomer.

The Cuban Health Department.

A despatch from Havana to *The Sun* of this city last week brought the disconcerting news that there had been a political upset in Cuba, and that as a consequence Dr. Duque, the present most efficient Secretary of Health and Charities, had resigned from the cabinet and would be succeeded by Sr. Alberoi. The same despatch stated that Dr. Juan Guiteras, Chief Sanitary Officer of Havana, had also resigned, giving as his reason for this step that the appropriation for sanitary work had been so seriously reduced that he could no longer accept responsibility for holding yellow fever in check. A similar report was sent out by the Associated Press correspondent in Havana. We are very pleased to say, however, that, in response to an inquiry regarding the truth of this report, Dr. Guiteras has cabled to the Medical Record the gratifying assurrance that both he and Dr. Duque will remain at their posts, and he adds that the sanitary conditions in the island continue to be excellent.

The Money Value of Sanitation.

A writer in *Harper's Weekly*, referring to the successful outcome of Dr. Doty's mosquito campaign, says that he has almost entirely rid Staten Island of the savage *Culex sollicitans* that has hitherto kept away no one knows how many potential residents and made life a burden during the summer months to those already there. He has also all but exterminated the malaria-bearing *Anopheles*. The conquest of the mosquito, the writer states, has increased the value of real estate on the island by hundreds of thousands of dollars; new houses are going up throughout its length and breadth, and residences that have long been inhabited only by caretakers are being rented.

News of the Week.

Life Insurance and Tuberculosis.—A new departure in life insurance work has recently been inaugurated by the Metropolitan Life Insurance Company in the endeavor to aid in the hygienic conditions of their policy holders and thus prolong their lives. The first step in this crusade has taken the form of a pamphlet, the title of which is "A War Upon Consumption," which treats of "The Nature of the Disease; Its Extent, Growth, and Spread; Its Cure and Prevention, including Friendly Advice to Persons Having Diseases of the Lungs." The pamphlet will be sent out to the

1,100 local agents of the company who will deliver one to each policyholder in their districts. Where cases of tuberculosis exist, policyholders are asked to write to the company, in order that information may be forwarded to them concerning nearby sanatoria, tuberculosis hospitals, dispensaries, antituberculosis associations, etc. In addition agents will be notified to give such service as may lie in their power to help the unfortunate policyholders to gain admission or treatment in the proper institutions. The pamphlet is eight pages in length and is published in ten languages. Another move under consideration by the company is the institution of a tuberculosis sanatorium for its policyholders. They have an option on several hundred acres of land to be used for this purpose. As the present law of the State limits the acquisition of real estate by insurance companies to "such as shall be requisite for its [the company's] convenient accommodation in the transaction of its business," there is some doubt as to the possibility of carrying out this latter plan. After a hearing on the question of the legality of such a hospital, held recently in New York, State Superintendent of Insurance Hotchkiss reserved decision. It is expected that the matter will be settled within a few weeks.

Examination for Health Officers.—It is announced by the Indiana State Board of Health that the first examination for those who wish to become eligible for appointment as County Health Commissioners or city or town health officers, will be held in the State house, Indianapolis, September 30. Physicians intending to enter the examination must make application on official blanks before September 23. Blanks and rules governing the examination may be secured from the State Board. The examination will cover generally the fields of hygiene and sanitary science, including drug and food inspection, health statutes, rules of the board, and vital statistics. Application blanks and pamphlets containing the health statutes and rules will be ready for distribution by the State Board of Health on and after August 10.

Reduction in Mortality from Tetanus.—The City of Chicago is to be congratulated upon the outcome of the recent, more rational Fourth of July celebration. "Three weeks have now elapsed," says the Bulletin of the Health Department, "and we can safely conclude as to the effects of this variety of observance. There has been but one death from tetanus during the last three weeks and that was not due to a Fourth of July accident. Last year in the same time there were four. This saving is due to three factors: (1) The use of safer explosives. (2) The lessened use of explosives. (3) The freer use of tetanus antitoxin as a preventive measure. We have not been able to trace a single death directly to explosives used on this occasion. The two Chicago deaths carried in the Chicago papers are but remotely connected with explosives. One was due to a runaway, in which the horse had been frightened by a cracker. The other was caused by an engine running to a fire caused by an explosive. The police should be thanked—the people congratulated."

Epidemic of Meningitis in Nebraska.—A distinctly localized but severe epidemic of cerebrospinal meningitis is reported in Nebraska. In and near the towns of Stromsburg, Osceola, and Benedict over a hundred cases have appeared within a few weeks. The State Board of Health has investigated the subject and has instituted a quarantine of the patients.

Cholera in Russia.—Dispatches from Polotsk, the only city in Russia, aside from St. Petersburg, where the cholera has made much headway, say the city is in a panic owing to the inefficiency of the sanitary administration and the shortage of physicians. Forty cases of cholera are reported daily.

Cholera and Plague in India.—One hundred and thirty-five bubonic and thirty-five cholera deaths were reported to the Amoy officials during the two weeks ended July 24. In the northern interior districts bubonic plague is decreasing, but in the south the disease is on the increase.

Antituberculosis Campaign in New York State.—The State Charities Aid Association of New York announces that at the State fair in Syracuse, and at each of forty-two county fairs this summer, will be shown exhibitions on the subject of tuberculosis. For this purpose six complete exhibitions are being prepared. These will be moved from place to place as the various fairs meet. The exhibits will tell by means of pictures, original charts, and accurate data the story of the extent, nature, growth, spread, cure, and prevention of the disease.

Physical Examinations for Marriage Licenses, as required by the new law in the State of Washington, is receiving the hearty support of the medical profession of that State. Their belief in the benefits to be derived from such a law, properly enforced, is shown by the resolution recently passed by the members of the Spokane County Medical Society agreeing to accept no fees for such examinations.

Report on National Vitality.—Mr. Irving Fisher has recently issued a report as the result of ten years' investigation upon public health questions in the United States. He states that this country is wasting each year a billion and a half dollars on preventable diseases. There are 3,000,000 persons needlessly and continuously ill in the United States from diseases which could be prevented by the simplest hygienic measures. Tuberculosis is responsible for 500,000 persons continuously ill. Typhoid fever costs the country $350,000,000 annually, and malaria $100,000,000. Both of these diseases could be stamped out if proper hygienic attention were paid to them.

The Boston Board of Health has adopted a regulation to the effect that all foodstuffs shown for sale in store windows or other places must be protected from dust and flies by screens or otherwise.

St. Luke's Hospital in New York is to have some improvements made in its laboratory facilities at the cost of $25,000. The bacteriological laboratory will be remodeled so as to improve its lighting and an animal room will be inaugurated.

New Hospital for Guadalupe Hidalgo.—This suburban town in Mexico is to have a thoroughly up-to-date hospital. It is to be built at once and inaugurated on the celebration of the Mexican centennial.

New Hospital in Woodhaven.—The Little Sisters of the Poor of St. Francis in Brooklyn are about to erect in Woodhaven a brick building for hospital purposes. The new hospital will be called St. Anthony's. It will be supported by voluntary contributions.

University Appointments.—Dr. J. F. Powers of Wake Forest has been elected dean of the medical department of Wake Forest College to succeed Dr. W. S. Rankin, who retired to become secretary of the State Board of Health. Dr. E. S. Cain has been appointed lecturer on clinical medicine and pharmacology, and Dr. A. D. West lecturer on clinical surgery and orthopedic surgery at the Memphis Hospital Medical College.

Dr. G. H. Sumner of Waterloo, Ia., has been elected Secretary of the Iowa State Board of Health. Dr. Sumner has been city health officer of Waterloo for the past seven years.

New Brunswick Medical Association.—At the annual meeting of this association, held at St. John, N. B., on July 20, the following officers were elected: *President,* Dr. H. A. Murray of Fredericton Junction; *Vice-Presidents,* Dr. C. T. Purdy of Moncton, and Dr. G. G. Melvin of St. John; *Treasurer,* Dr. D. E. Berryman of St. John; *Corresponding Secretary,* Dr. J. S. Bentley of St. John; *Recording Secretary,* Dr. G. G. Corbet of St. John; *Trustees,* Dr. T. H. Lunney, Dr. C. H. L. Johnston, Dr. R. C. Ruddick of St. John.

The Addison County (Vt.) Medical Society, meeting at Montpelier recently, elected the following officers for the coming year: *President,* Dr. George F. B. Willard of Vergennes; *Vice-President,* Dr R. W. Bentiss of East Middlebury; *Secretary,* Dr. F. H. Phelps of Vergennes; *Treasurer,* Dr. F. C. Briggs of Bristol; *Librarian,* Dr. M. H. Eddy of Middlebury.

American Electrotherapeutic Association.—The annual meeting of this Association will be held in New York City on September 28, 29, and 30, instead of September 14, 15, and 16, as first announced. The president of the Association is Dr. Edward C. Titus of this city, and the secretary, Dr. J. W. Travell, 27 East Eleventh street, New York.

German Surgical Society.—The next annual meeting of this Society will be held at Langenbeckhaus, Berlin, in April, 1910, under the presidency of Prof. Bier of Berlin. The secretary is Prof. Dr. W. Körte, Kurfürstenstrasse 114, Berlin.

Obituary Notes.—Dr. Matthew Turner Newton of Suffield, Conn., died at his home on July 24, 1909, aged 80 years. Dr. Newton was a graduate of the Yale Medical College in 1851. After graduation he began practice in Salem, Conn., and in 1853 was elected to represent his town in the Connecticut Legislature. Shortly afterward he removed to Suffield. During the Civil War he served as Assistant Surgeon in the Third Connecticut Volunteers and as Surgeon in the Tenth Connecticut Volunteers. In 1893 Dr. Newton was again elected to the Connecticut Legislature where he acted as chairman of the Committee on Humane Institutions. He was chairman of the executive committee of the trustees of the Connecticut Library Institution, a director of the Suffield Public Library, and a member of the Hartford County Medical Association and the Connecticut Medical Society. Dr. Newton was one of the best known of the older physicians in his State.

Dr. Joseph Anderson of Denver, Colo., died on July 18. Dr. Anderson was a veteran of the confederate army, and one of the pioneers of Colorado. He was seventy-seven years of age.

Dr. C. Dustin Hunking of Haverhill, Mass., died suddenly at his summer home, at Hampton Beach, on July 23, 1909, at the age of 59 years. He was a graduate of Harvard University in 1871. After studying medicine in Vienna and Strasburg he returned and completed his studies in the Harvard Medical School, from which he graduated in 1877. Dr. Hunking was a man of many interests outside of medicine. He was treasurer of a real estate improvement company, a member of a drug firm, and at one time joint owner and publisher of the *Haverhill Gazette.*

Dr. Albert M. Curry of Brooklyn dropped dead on the beach at Atlantic City on July 26, 1909. Dr. Curry was a graduate of the medical department of the University of Pennsylvania in 1875. He was a member of the Kings County Medical Society and the New York State Medical Association.

Dr. Ernst Jacob of Cincinnati, Ohio, died in that city, July, 1909. He was a graduate of the Miami Medical College in 1889.

Dr. Wesley G. Matchan, formerly of Minneapolis, died July 21, 1909, at Bismarck, N. D., aged 33 years. Dr. Matchan was a graduate of the University of Minnesota, a member of the staff of Governor John Burke, and head physician for the Northern Pacific Railroad. He was also physician for the North Dakota State prison at Bismarck.

Dr. Homer Lycurgus Law of Hartford, Conn., a retired surgeon of the United States Navy, died at his home on July 17, aged 61 years. He was a graduate of the Jefferson Medical College in 1869. He entered the service of the United States navy in 1870 as assistant surgeon, being appointed from Pennsylvania, and in 1875 was made past assistant surgeon. In 1884 he was appointed surgeon and in 1886 was placed on the retired list. In the Spanish-American War in 1898 he was again called upon for active duty. He was chairman of the executive committee of the Hartford Medical Society and a member of the Hartford County Medical Association, and the Connecticut Medical Society.

Dr. Willis P. King of Kansas City died July 12, 1909, aged 70 years. He was a graduate of the St. Louis College of Physicians and Surgeons in the class of 1866. Dr. King was one of the pioneers of Missouri, having spent many of his earlier years in the arduous life of the frontier circuit riding country doctor.

Dr. Bowditch Morton, formerly of New York, died suddenly of heart disease at Long Beach, Cal., on July 17, 1909. Dr. Morton who was in the West for his health was the son of the late Dr. Thomas Morton of Boston.

Dr. Robert W. Muhleman of Bellaire, Ohio, died at his home on July 18, 1909, aged 53 years. He was a graduate of the Pulte Medical College in 1877. He was a prominent physician of Bellaire, where he had practised since his graduation.

Dr. John E. Redmond of Salt Lake City died in that city, July 19, 1909, aged 24 years. Dr. Redmond, on graduation from the medical department of the Northwestern University in Chicago in 1908, was appointed to the house staff of the Cook County Hospital. Failing health, however, compelled him to resign and move West. In Salt Lake City he was appointed assistant pathologist and bacteriologist to the Holy Cross Hospital. He was a member of the Salt Lake County Medical Society, the Utah State Medical Association, and the American Medical Association.

Correspondence.

POSSIBLE INFECTION THROUGH RAGS.

To the Editor of the Medical Record:

Sir:—I was very much interested in your recent editorial on "The Fomites Theory of Disease Transmission" and would like to recite one specific case in favor of the theory as regards scarlet fever.

Many years ago I was called into the country to see a little girl who was ill with scarlet fever. I was just out of college and was an enthusiastic investigator, so I attempted to ascertain the source of the infection. The people were well to do; the surroundings were all that could be desired; the house and everything about it was clean. The child had never been away from home nor had the parents visited a house where there had been scarlet fever, nor had any one visited the house from an infected region. I was at a loss for many weeks to know where the infection came from. Finally the mother made the statement that a few weeks before the child was taken down with the disease, she had received some rags to be used for carpet rags from a relative who lived miles away and that the child had been playing with them. In this case the source of infection was clear, for in the house whence came the rags there had been a case of scarlet fever two years previous.

Galesburg, Ill.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER RESEARCH FUND—ANTIVIVISECTIONISTS IN CONGRESS—DESTRUCTION OF RATS IN AUSTRALIA—RESEARCH DEFENSE SOCIETY—CONGENITAL STENOSIS OF THE PYLORUS—DR. COLEY AT THE R. S. M.—ITEMS.

London, July 16, 1909.

The seventh yearly meeting of the Cancer Research Fund's General Committee attracted additional attention from the explanation which was expected as to the decision not to unite with the German or the proposed international societies. The Prince of Wales, as president, took the chair, and the gathering was held at Marlborough House. No doubt you are aware of some of the reasons why the proposal of international amalgamation does not commend itself to the workers of our Fund, but it may be well to have the official view of the matter. The report mentions the fact that the German society had addressed the King on the proposal during His Majesty's visit to Berlin. After consultation with the officials and the director the King replied through the Foreign Office that the Fund had cooperated freely in the past both with German and other foreign workers and would continue to do so in the future. Referring to this in his address, the Prince-president stated that he had seen all the correspondence that took place and all the proceedings were submitted to him. He then added that he had given his approval, as he was convinced that the methods adopted by the Fund of freely distributing their material to workers in every country, of permitting anyone with satisfactory credentials to study the methods in their laboratories, and encouraging international collaboration among the workers in the various cancer laboratories, are the wisest and most efficient means of advancing the study of the disease. His Royal Highness referred to other parts of the report and expressed the belief that the seven years' work had brought about a complete change in the standpoints from which cancer is studied and that many various lines of research are being pursued with the minutest care and utmost perseverance. He held, further, that the number of applicants to work under the superintendent, coming, as they do, from all parts of Europe, from the United States, and from Japan, shows the high value attached to work in the Fund's laboratories.

Sir W. Church, in moving the report, said the last year's work confirmed his opinion that the study of the disease in mice formed a sound foundation for its study in the human species. The immunization of animals, if established, would afford another point. The effects of radium was another. The failure of attempts to obtain an anticancerous serum led to attempts to separate, if possible, from cancer cells immunizing powers apart from their continued growth and propagation. Thanks to the seven years' work, he maintained the disease now stood in a very different position, but it was premtaure to hold a general conference.

Sir Henry Morris seconded the motion, which was adopted. As treasurer he had to announce another deficit. Since 1903 no less than £9,915 had been taken out of capital to meet yearly recurring deficiencies. In the year just closed the revenue was exceeded by more than £2,000 and unless substantial help is forthcoming the trustees will be obliged to realize at least £1,000 forthwith. Moreover, the changed ownership of the examination hall may necessitate building new premises. Hitherto the generosity of the two royal colleges has saved this expense. It is to be hoped that the needs of this important work will be shortly met.

Two hundred delegates from thirty countries met last week in London for a conference as an antivivisection and animal protection congress. The opener said their hope was not in the idle rich, but in workers, and every laborer in Parliament was with them. The old "World League" was reconstituted into an International Federation, but not without strong opposition. The object seemed to be to include all societies which advocated kindness to animals in any way—even veterinary hospitals, dog homes, the lethal chamber, and so on; but the abolition of vivisection was the center of the agitation. Medals were presented to the chairman and others. In his reply he said if the women of this country knew what was going on behind the scenes they would express abhorrence of what was done in the name of science, and he hoped to see the day when the most noble of professions would be cleansed of this disgrace of vivisection. Others used more violent denunciations. Of course, such extremists went in for a procession to wind up their congress. They succeeded in having a fairly large one, though small in comparison with the amused lookers-on. One of these informs me that part of it was very pretty, especially the women with their pet dogs duly dressed and either led or carried. House ambulances, the animals' hospital, the drivers, the humane work of giving oatmeal and water to cab horses, etc., on hot, sunny days, were all represented. Then came half a dozen donkey carts and as many pony traps, three ladies on horseback to represent the Anti-Bearing Rein Association, and, besides, other demonstrators, the Theosophical Society! Banners with strange devices, speechmaking in the park and resolutions that vivisection is immoral, and calling on Parliament to repeal the acts concluded the demonstration. Future congresses are to be at two years interval—the next at Copenhagen and the one after it in the United States. So you must wait for it for four years. Be patient.

There seems to have been a split among these united agitators for the "World League," which devotes itself to total abolition, advertises that it will treat us next week to another congress—its fourth triennial and international—on the same lines, procession, speeches in the park, and other features of the demonstration.

Some of the most extreme agitators went so far as to assert that medical science had done nothing for epidemics like plague. Evidently they had not heard the late news from Australia on this point. How at Brisbane, where it prevailed for several successive years, the destruction of rats and mice to the number of nearly 20,000 had prevented its recurrence. How, in all Queensland, some 35,000 of these animals had been destroyed, about half of them had been carefully examined, the result being most satisfactory.

Of course the Research Defense Society could not descend to the methods of the antis; but the secretary (Mr. Stephen Paget) has sent a letter to the press inviting those who would like to study, quietly at home, the truth about experiments on animals, under the restrictions of the acts, to apply to him for literature on the subject, and, if convinced, to become subscribers to the society. He adds that the committee is making arrangements to extend the society's work during the coming winter by lantern lectures, the distribution of literature and the formation of branches.

I hope the literature sent out will include the forcible speech of Lord Cromer as president of the annual meeting on the 24th ult., when, in the course of a most clear and convincing account of the work, he declared that any one who took the trouble to read the evidence before the Royal Commission would find that there was not a single alleged case of extreme or unnecessary cruelty brought forward by the antivivisection society which did not hopelessly break down under cross-examination.

In the Section for Diseases of Children of the Royal Society of Medicine Dr. G. Carpenter showed 3 specimens. (1) Hypertrophic stenosis of pylorus from a

female infant of three weeks. When admitted it was not considered fit for operation. (2) Morbus cordis with transposition of viscera, a cyst in the tongue, and a solitary kidney. (3) Congenital dilatation of the colon. This was from a child shown at a former meeting of the section, when the suggested diagnosis was not accepted by all. Later the child wasted more rapidly and the large colon could be seen through the abdominal wall, and contraction was easily excited by flipping with the finger. The colon measures 17½ inches, and is about 5 inches in circumference at the widest part. Dilatation begins at the ileocecal valve and ends at the rectum. No ulceration of the mucous membrane.

Mr. Clinton Dent demonstrated by cinematograph the movements of the stomach as seen through the abdominal wall in a child at eight weeks with hypertrophic stenosis of the pylorus. At birth the child weighed 8 pounds, on admission to hospital 5; this was 11 days before death, operation not having been considered safe.

On Tuesday last the Surgical Section had the pleasure of a lecture by Dr. W. B. Coley, from your city, on his treatment of sarcoma by bacterial toxins. He said he had successfully treated 52 inoperable cases, of which 35 remained well after from 3½ to 16 years; 28 after 5 to 16, and 14 after 10 to 16 years. In all but 2 out of the whole 52, microscopic examination confirmed the diagnosis. About 100 successes had been reported by other surgeons. In reference to the slowness of acceptance by the profession of his views he said history clearly proved that there was no relation between the value of any discovery and its general acceptance. A vote of thanks was carried by acclamation on the proposal of Mr. Butlin, seconded by Sir A. Wright.

The first number of "Heart: A Journal for the Study of the Circulation," has appeared under the editorship of Dr. Thomas Lewis, assisted by a strong staff of British and American experts. It is intended to include only original work on the subject.

Mr. H. T. Butlin has been elected the new president of the Royal College of Surgeons. Mr. Pearce Gould and Mr. R. C. Lucas are the vice-presidents.

Mr. Bowerman Jessett has resigned the office of senior surgeon to the Cancer Hospital.

A farewell banquet was given to Sir F. Semon on the 2d inst. on the occasion of his retiring from practice.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

JOINED TWINS—HARMFUL MOSQUITOS—CRUDE CHAULMOOGRA OIL IN LEPROSY—CULTIVATION OF THE LEPROSY BACILLUS—TRANSPLANTING CHOLERA CULTURES—PERSONAL.

MANILA, P. I., June 21, 1909.

THE regular monthly meeting of the Manila Medical Society was held in the lecture room of the Philippine Medical School, June 7, 8:30 P.M.

Dr. Valdez, the professor of practice of medicine at the Santo Tomás University, exhibited a case of male twins six months of age, of Filipino parentage, who were firmly joined together, apparently by osseous union of the two sacra. Each child was apparently a complete anatomical unit in itself, with the exception of the anus, which served for both children.

Captain Rutherford, assistant surgeon, U. S. Army, exhibited a number of eye cases, one of which was a case of detached retina.

Dr. Charles S. Banks, entomologist of the Bureau of Science, gave a talk upon the harmful species of mosquitos in the Philippines and their morphology. Among other things of interest he stated that the mosquito which had been heretofore known as the *Stegomyia fasciata*, and which was so abundant in the Philippines, was, in all probability, the *Stegomyia perstans*. Also, that Theobold had practically come to the conclusion that the Philippine mosquito which he had previously described as the *Myzomyia ludlowii* was in all probability the *Myzomyia rossii*. In the discussion which followed Dr. R. P. Strong laid special stress upon the fact that much confusion existed at present with regard to the classification of Philippine mosquitos, and that this was a serious handicap in the study of tropical diseases.

A paper by Dr. A. J. McLaughlin, the Assistant Director of Health, entitled "Sanitary Measures Against Mosquitos," was read by the secretary. He outlined the attitude of the Bureau of Health toward the eradication of this annoying and dangerous pest. The local health authorities have had considerable criticism heaped upon them for not taking more measures looking toward relief. In explanation of this, Dr. McLaughlin stated that much relief might be had if the householders themselves would destroy the purely domestic breeding places, like rain barrels, fire buckets, cisterns, tanks, and other places directly under their control. However, the great source of mosquitos in Manila were the great tidal swamps which were daily overflowed by the water in the esteros or canals not being confined to their walls, and on this account it was a waste of public funds to attempt the temporary measures which often proved successful in other countries. He was of the opinion that in spite of the fact that it was estimated that several million dollars would be necessary to fill in the low lands and to wall the esteros, the resulting gain in the increased value of real estate would more than offset the original expense, and that until this was done Manila could scarcely be expected to have a permament low mortality rate.

Since the treatment of leprosy with crude chaulmoogra oil, as recommended by Dyer, was begun by the Bureau of Health, the results have been much more encouraging. Two cases that have been under treatment at Culion clinically have the appearance of having completely recovered. All of the nodules or tubercles, some of which were several centimeters in size, have been completely absorbed and the leprous dermatitis has entirely disappeared. It was only after many specimens for microscopical examination were taken that a few scattered bacilli could be found.

In this connection it may be interesting to note that since the paper which was read at the annual meeting of the Philippine Islands Medical Association by Dr. Moses T. Clegg, in which he reported having apparently cultivated leprosy bacilli from cultures which were taken from the spleen of leprous subjects at post mortem, he has succeeded in cultivating the bacilli from cultures taken from the ear of live cases, and that the technique has been verified so frequently that there can be little doubt but what true leprosy bacilli are being actually grown. In addition, there has now been made a vaccine from these cultures which, when injected into leprous persons, produces a most pronounced reaction in the leprous lesions. The results along this line will shortly be reported before the Manila Medical Society.

Lately the Bureau of Health has used a method of transporting cholera cultures over long distances, and especially where a number of days must elapse before they can reach the laboratory, which has proved very successful in practice and has done much to verify the diagnoses which are made in remote sections of the islands. Some peptone is inoculated with a specimen of the stool and allowed to grow for twelve hours; transplants are then made upon agar tubes and these are then placed in mailing cases and sent to the laboratory. Heretofore the difficulty has been that extraneous organisms in the peptone culture soon overgrew the cholera spirilli and that none of the latter could be recovered.

J. R. Hurley, assistant surgeon, P. H. and M. H. S., who was formerly one of the quarantine officers on duty at San Francisco, has been transferred to the Philippines and is now on duty at Manila.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 22, 1909

The Bearing of the Experimental Investigation of Tumors on the Tumor Problem in General.—E. F. Tyzzer says that the pessimism sometimes expressed concerning the cancer problem serves only to discourage investigation. It is evidently based in many instances on the assumption that all tumors arise from congenital defects or abnormalities. The successive description and exploitation of a long list of pseudo-parasites has served to bring discredit to this field of investigation, and the inadequacy of various theories advanced concerning the origin of tumors have served to strengthen the doubt. It is sometimes stated that there is no advance in our knowledge of tumors. In addition to the establishment by clinical observation of the part played by chronic inflammation, the experimental investigation of tumors has yielded certain definite results, which show such statements to be erroneous. It is

proven by transplantation experiments that cancer cells differ biologically by their property of unlimited growth from normal tissue cells. Peculiar conditions are not essential for the continuation of this growth. Certain tumors grow in normal individuals. Other tumors, however, require a special soil; they grow if transplanted into other parts of the same individual, but not if transplanted into other individuals. Growth is found to depend upon the biological character of the cells and not upon their dislocation. The experimental investigations have made untenable the interpretation of cancer as an infectious disease. The development of sarcoma in animals inoculated with epithelial tumors is interpreted by most investigators with whom it has occurred to be the result of the irritating influence of the tumor epithelium. The demonstration of the presence of substances which prepare tissue for growth on subsequent injury or stimulation is of great importance. There is, therefore, no more basis for pessimism with regard to the tumor problem than there was formerly for a similar attitude with respect to the problem of the infectious diseases. The essential problem is one of growth and its investigation concerns the biologist, the zoologist, and the embryologist, as well as the physician.

An Epidemic of Infantile Paralysis in Western Massachusetts in 1908.—Herbert C. Emerson deals with the groups of diseases attacking children chiefly, but youths and adults frequently up to the age of 25 years, among the inhabitants of river valleys, in sparsely settled communities, occurring during the summer months of a hot, dry season. Ninety per cent. of the persons attacked were in good health. The investigation of this group of cases suggests that the disease is but mildly contagious. The sanitary conditions under which most of the cases lived were not good. Dampness prevailed in many localities. Most of the houses had no sewer connection. The marked digestive disturbances, which were early and notable symptoms, suggest the stomach as the port of entry for the infection. That the cause may be connected with the food seems possible. From an intimate acquaintance with all the facts and conditions of this outbreak he concludes: (1) That infantile paralysis is a disease produced by some external agent; that is, it is an infectious disease; (2) that it is mildly contagious at the most; (3) that the harmful agent appears to enter the digestive tract in most instances; (4) but that until the organism causing the disease is known, it would be impossible to say whether the infection is carried directly to the patient or by means of food.

The New York Medical Journal, July 24, 1909.

Some Conditions in the Growth of Tumors.—Leo Loeb formulates the cancer problem in three questions: (1) Under what conditions does a tissue assume an increased energy of growth? (2) Under what conditions does a hereditary transmission of an acquired increase of growth energy to the succeeding cell generations take place? (3) Why do we find an infiltrated growth in cancer? An increase in the energy of tissue growth can be accomplished by wounding the tissue. Such a regenerative proliferation usually leads merely to the replacement of lost cells, and ceases as soon as the wound has healed. If incisions are made into the uterus of a guinea pig during the first nine days after the rupture of a follicle, each cut, or almost each cut, leads to the formation of a tumorlike deciduoma. During the early period of its existence the corpus luteum secretes a chemical body which unites with the mucosa of the uterus and acts as a sensitizer, sensitizing the mucosa and leading it to act in a different way, that is leading to the production of tumorlike new formations where ordinarily the uterus would only have shown the processes of wound healing. In order to obtain a tumorlike growth we must look for a combination of factors, namely, the action of a chemical sensitizing substance and of an external exciting cause. Therefore, we have not been able to produce cancer through trauma because of a lack of knowledge of the internal factors. There exists in all likelihood a correlation between internal sensitizing and external stimulating factors of such a character that the stronger the one set of factors is represented, the less is required of the second set of conditions. External stimuli, such as the long-continued use of arsenic or the long-continued use of Röentgen rays, represent an important set of factors in the etiology of cancer of the skin, and it is reasonable to assume that cancer of the internal organs is preceded by stimuli which have acted over an extended period. The importance of external stimuli in causing proliferation of tissue not only applies to normal tissues and to those in process of transformation into tumors, but also to cancer cells. An increase can be produced through mechanical stimuli, as cutting into the tumor or by pulling a thread through its entire diameter. In a similar way, in the serial transplantation of tumors there is usually an increase in the energy of growth. This, however, does not apply to all tumors. Not all are equally affected by mechanical irritation. An occasional transformation of a benign to a malignant tumor, after an operation, is due to mechanical stimulation and not to changes in the blood supply. Abnormalities in embryonal development, which lead to the misplacement of tissue, and to the formation of teratomata, which cause such insignificant conditions as pigmented moles, were especially liable to form cancer. Stimuli which in normal tissues would be harmless lead here not infrequently to the formation of malignant tumors. It is, therefore, expected that tumors resulting from such embryonal malformations should likewise sometimes be hereditary. Not only the hereditary transmission of anatomical developmental peculiarities, but also of invisible metabolic or functional conditions may, in all probability, occasionally lead to the extraordinary frequency of cancer cases in certain families. Under what conditions the hereditary transmission of the increase in the energy of growth takes place is as yet very little understood. Dr. Loeb has found that the increase of growth energy accompanying regenerative processes is not transmitted into the succeeding generations of cells: on the other hand, at least a temporary transmission of the increase in growth energy acquired through stimulation of the lens of certain amphibia by ether takes place, according to Reinke. From certain clinical evidence it seems that transmission can be induced. The presence of intracellular micro-organisms can explain such a hereditary transmission in the increase in the energy of growth, but it was by no means necessary to take refuge in such an interpretation for all cases. There is one interesting condition which seems especially to call for the presence of microorganisms, namely, the endemic occurrence of cancer, which is so very much more striking among animals than among man.

Colles's Fracture, with Special Reference to the Lateral Deformity.—Paul P. Swett discusses that variety of Colles's fracture wherein there is a transverse fracture of the lower end of the radius with displacement of the lower fragment upward and backward, elevation of the radial styloid, lateral displacement of the hand outward, and widening of the wrist below the site of the fracture. The probable immediate effects of a fracture with displacement of the lower end of the radius are: Lateral and upward displacement of the lower radial fragment with impaction of the lower end of the upper fragment into it. Fracture of the ulnar styloid, rupture of the ligaments of the wrist joint, and rupture of the interarticular fibrocartilage. A study of the mechanism of Colles's fracture shows that there are severe injuries to ligaments and to cartilage which place it in a class by itself and which serve to explain some of the difficulties attending its successful treatment. Ligaments and cartilage when only partly healed are more susceptible to strain than when uninjured. Frequently repeated slight strains produce a traumatic inflammation that closely simulates rheumatoid arthritis and is often mistaken for it. Muscles and tendons atrophied from disuse are more easily strained than active muscles. Protection must be continued for a longer period of time than when these structures are not injured. Passive movements must not be attempted too early, and resumption of function is to be gradually undertaken, and no effort that tires or strains the wrist is to be made. The form of splint is not of so much importance as the way in which it is employed. A single palmar splint, well padded, expending from below the elbow to a little beyond the fingers accomplishes the purpose of immobilizing the fracture and providing support for the injured wrist, hand, and forearm. The splint is padded thickly with gauze just behind the palm and thus maintains the wrist in slight palmar flexion. A fold of this gauze pad is extended around the ulnar side of the wrist and is a guard against slumping of the ulnar head. In very severe cases a strip of adhesive plaster around the wrist, outside of the gauze pad, is valuable in holding the ulnar head more securely. Complete rest for the part cannot be secured with a short splint that terminates at the palm, and the longer one should be used for the first three or four weeks. For the first forty-eight hours it is well to keep the whole appliance wet with water, as this lessens pain and swelling. Immobilization should be continued for at least six weeks in the moderate cases, and for eight weeks or longer in the more severe cases, as a rule. Early passive motion in these cases is especially contraindicated

because the stretching of the torn ligamentous fibers thus induced is particularly injurious. Gentle massage of the skin is indicated, however, where there is the least sign of edematous swelling. After the removal of the splint a leather and steel wristlet is of the greatest advantage. This is a simple wristlet extending from the palm of the hand half or two-thirds way to the elbow. It is reinforced with a light piece of steel in the palm and is made to lace so that it can be removed at will, and thus one may gradually lengthen the periods when the wrist is used without protection..

The X-Ray for the General Practitioner.—Samuel McClary says that a general practitioner has no right to use a drug until he knows its strength, the dosage, and the effect to be expected. He must regard *x*-rays in like manner, and should not attempt to use them until he receives considerable instruction from a competent person, preferably a physician, who has had a large experience, and even then he should start in very cautiously. Mechanical measures of dosage are useful, but one must not rely on them alone. Dr. McClary offers the following general suggestions: 1. Operators should always keep back of the active hemisphere of the tube and never use the hand fluoroscope. 2. Use a protective shield on the tube and protect the other parts of the body that it is not necessary to expose to the rays. 3. Burns are more easily produced where the circulation is the poorest. 4. When reaction is set up, stop treatment until it subsides, as you may burn the patient badly. 5. A new tube should be used very cautiously until its characteristics are known. 6. Be careful of both yourself and the patient. Dr. McClary gives concise directions for the use of the *x*-ray by the general practitioner in many cases such as fractures, foreign bodies, malignant disease, skin diseases, tuberculous glands and sinuses, to outline organs, such as the stomach, and to locate unerupted teeth. He is also of the opinion that the radiographer gets the best results who develops his own plates.

Journal of the American Medical Association, July 24, 1909.

The Hypophysis Cerebri.—Harvey Cushing says the hypophysis of all animals contains a blood-pressure-raising principle, confined to the posterior lobe and restricted to the pars nervosa of this lobe. An extract of this lobe has a marked diuretic effect on the kidneys. This substance seems to be akin to adrenalin, one striking resemblance being the pupillary dilatation which both produce when instilled into the eye. It has been found by S. J. Crowe that successive injections of posterior lobe extract soon fail to raise blood pressure and that repeated daily injections are very deleterious and may even be fatal; they cause extreme tissue changes especially in the liver. This is the main part of what injection methods have taught us of the function of the pituitary body and nothing at all in fact of the function of the anterior lobe which would seem histologically the most important part of the gland. As yet, most of the available preparations contain the extract of both lobes and it can be seen that we are far from a satisfactory organotherapy of the hypophysis. These experimental results pertain to an overactivity of one or another part of the gland. The reverse condition of diminished secretion and its effects could be more easily investigated were it not for the inaccessible position in which the organ is placed. Many investigators have endeavored to reach it safely in experimental animals, but all routes are difficult. Cushing says that the total removal of the gland leads in the course of days, or at the most, of weeks, to death with peculiar and characteristic symptoms. The anatomical separation of the anterior from the posterior lobe by a persisting cleft makes it possible to remove either one of them separately in the dog, the posterior more easily than the anterior. No particularly characteristic symptoms, except possibly some sexual disturbances, appear to follow the removal of the posterior lobe. The case is otherwise with the anterior one, the removal of which produces profound alteration. Cushing summarizes the results as follows: "Two conditions, one due to a pathologically increased activity of the pars anterior of the hypophysis (hyperpituitarism), the other to a diminished activity of the same epithelial structure (hypopituitarism), seem capable of clinical differentiation. The former expresses itself chiefly as a process of overgrowth—gigantism when originating in youth, acromegaly when originating in adult life. The latter expresses itself chiefly as an excessive, often a rapid, deposition of fat with persistence of infantile sexual characteristics when the process dates from youth, and a tendency toward a loss of the acquired sign of adolescence when it first appears in adult life. Experimental observations show not only that the anterior lobe of the hypophysis is a structure of such importance that a condition of apituitarism is incompatible with the long maintenance of life, but also that its partial removal leads to symptoms comparable to those which we regard as characteristic of lessened secretion (hypopituitarism) in man. A tumor of the gland itself, or one arising in its neighborhood and implicating the gland by pressure, is naturally the lesion to which one or the other of these conditions has heretofore been attributed, though it is probable that over-secretion from simple hypertrophy, or under-secretion from atrophy, will be found to occur irrespective of tumor growth when examination of the pituitary body becomes a routine measure in the postmortem examination of all cases in which the conditions suggest one or the other of the symptoms complex described. When due to tumor, surgery is the treatment that these conditions demand, and at present there are reasonably satisfactory ways of approaching the gland; but clinicians and surgeons must clearly distinguish between the local manifestations of the neoplasm due to involvement of structures in its neighborhood other than the hypophysis, and those of a general character from disturbances of metabolism due to alterations of the hypophysis itself."

Optic Atrophy in Tabes.—E. D. Fisher believes the concept, generally maintained, of general paresis is too comprehensive and that the cases continuing over long periods belong to another pathologic state than the type which pursues a briefer course with fulminant active symptoms ending in complete dementia and having also spinal complications involving both lateral and posterior columns. The pathological findings in the more protracted cases are, he thinks, not distinctive of general paresis but are also found in other conditions of arterial degeneration. Other points of differential diagnosis may be suggested by the question whether paresis and tabes are the same disorder. Fisher believes, however, that they are distinct diseases, no typical case of tabes ever passing into general paresis. He thinks that in those cases in which the paretic symptoms were preceded by ataxia, the so-called tabic form of paresis, the pathological spinal cord changes are more diffuse than in typical tabes. The comparative infrequency of pain in paresis and its difference in type when it occurs from that of tabes is one diagnostic point, although there are great variations in individual cases. Added to this point he wishes to call attention to another differentiating symptom, namely, the occurrence of optic atrophy in tabes and its infrequency or absence in paresis. He gives the statements from a number of physicians of the New York State hospitals who testify that this symptom is one of the rarest in paresis. He thinks we are including too many diseases under the common name of paresis.

Morphea-Like Epithelioma.—Premising his remarks with the statement that, so far as he knows, this form of epithelioma has not yet been mentioned in text books on surgery, and is only very briefly alluded to in one work on skin diseases, M. B. Hartzell reports three cases of morphea-like epithelioma. The first patient was temporarily cured by *x*-ray treatment, as was the case with the patient in the second case, which was of interest on account of the early age at which the disease appeared, the patient being only twenty-four. The third case was of more special interest because it was microscopically diagnosed, this not having been permitted in the other two. In all three the disease began as a smooth slightly elevated plaque, of a yellowish-white or yellowish-pink tint, over which numerous small blood-vessels ran, gradually increasing in size and after some time developing ulceration with usually sharp margin. Hartzell reviews the literature of the subject. The progress in these cases was slow and without marked subjective symptoms. Stellwagon seems to be the only text-book author who refers to the subject, and he merely alludes briefly to the possibility of the epithelioma resembling morphea in his treatise on diseases of the skin. In the third edition of Crocker's well-known work, page 1012, the author refers to a case of rodent ulcer, unique in his experience, which Hartzell thinks certainly must have been one of this sort of epithelioma.

Mooren's Ulcer.—R. L. Randolph doubts whether it is possible clinically to identify a rodent ulcer in its first stages, and thinks that, even after the disease has lasted many weeks, it is very probable that many of us would not see more in it than an ordinary severe corneal ulcer. Yet there was in the only case he has seen one feature at least differing from any ordinary corneal ulcer he has ever met with, and that was the deeply undermined conjunctival edge of the ulcer. The edges of marginal ulcers are generally undermined, but, owing to the better blood supply at the conjunctival edge, this edge of the ulcer is

not conspicuously undermined except probably in the case of rodent ulcer. In the case here described by Randolph, the corneal edge was distinctly undermined and the conjunctival edge could be lifted up and was undermined for at least four or five mm. from the border of the cornea. Chronicity is characteristic in rodent ulcer. Its average duration is ten months and it may be longer. The disease would seem to be somewhat more frequent in Japan, according to the number of cases reported by Japanese observers. It is a mistake to think that the disease is a painless one, for it is characterized by frequent attacks of suffering and irritative symptoms generally. The ulcer shows a decided tendency to keep close to the limbus of the cornea and one of its peculiarities is a tendency to clear up and apparently disappear and then suddenly relapse. In most cases the disease dies out after the whole cornea has been involved, but exceptionally recurrences take place. As a rule, it is seen in individuals over forty and probably is never seen in children. Men are more liable to it than women and it is not infrequently found in both eyes, though Randolph doubts its simultaneous occurrence in both. We are in the dark as to its etiology though there are some that claim that disturbances in the sensitive nerve endings are somewhat responsible. Randolph could find no positive evidence of anesthesia except when the nerve endings had been destroyed and he is inclined to think that the disease is of bacterial origin. He says: "When one meets a corneal ulcer along the margin, careful examination should be made to ascertain whether the limbus edge of the ulcer is deeply undermined. If so the cautery should be applied at once, and it might be well to cut away with a delicate pair of scissors the overhanging edges of the ulcer so that parts underneath can be readily reached. If the disease shows no substantial improvement at the end of two months, I think it best to stop all irritating applications and simply continue with atrophine and salt solution irrigations and tonic treatment. I am not at all satisfied that repeated applications of the galvanocautery are advisable, such applications often being followed by a denser opacity than is produced by the actual ulceration.

Vitality of the Dental Enamel.—R. R. Andrews discusses the question of the vitality of the dental enamel which has been for some time a battleground for eminent authorities both here and abroad. He described the embryonic development of the enamel at length, and while he praises Dr. Bodecker's work on the subject he does not agree with him in his conclusions as to the vitality of the structure. For many years he gave most of his leisure time to the study of this structure and he has never been able to find a trace of the regular system of living fibers between the enamel rods that are described by Bodecker. It is a question yet to be decided how far the cement substance between the enamel rods is a vital tissue and he does not, with his present knowledge, believe that it is a vital tissue or that it has the same power of vitalization as to have fibers which are formed in the dentinal canals. It resembles somewhat the sheath tissue of the dentinal canals, which is not a vitalizing tissue, because we can see the vital fiber within its core sending off its anastomosing branches through the sheath tissue to other vital offshoots from other canals. This sheath tissue is also a transitional tissue, which becomes calcified into calcified matrix as age comes on. We may assume, he says, that the scanty vitality found in young enamel is given to it by a very thin organic layer of dentine origin between the dentine and enamel called the interzonal layer, together with an ingrowth of some of the processes of the dental forming cells which have invaded the enamel substance prior to its calcification. In some substances he has found these processes nearly reaching the outer surface of the fully formed enamel. They seem to become flattened and compressed by the force exerted by the enamel rods while they are calcifying and are very irregular in their course, most frequently running obliquely across the enamel rods.

The Lancet, July 17, 1909.

Notes on the Use of X-Rays in the Treatment of Malignant Disease.—S. E. Iredell reports on 31 cases of malignant disease, excluding rodent ulcer, treated with the *x*-ray. Of these, 23 were inoperable, the remaining eight having been sent immediately after operation for *x*-ray treatment in order to prevent recurrences. The effect of treatment most frequently observed in the inoperable cases was the relief of pain. In thirteen cases this relief was well marked and extended over weeks or months. The relief of pain was followed by a diminution of the size, and in some cases the disappearance of the tumors. Malignant glands in the neck and axilla, subcutaneous nodules in the skin, and in one case a secondary deposit in the sternum two inches in diameter cleared up. In malignant ulcers the relief of pain was followed by a diminution of the discharge; if offensive it loses its foul smell, and finally the ulcer may heal. In conclusion he says: (1) In superficial forms of malignant disease *x*-rays may temporarily arrest the course of the disease, diminish the discharge, and heal up the ulcers. (2) Probably *x*-rays prevent the occurrence of superficial secondary deposits. (3) Embryonic cells are more easily destroyed by *x*-rays than are normal cells.

A Case of Severe Facial Carbuncle, with Ludwig's Angina and Parotitis.—H. B. Walters and R. V. Solly report such a case successfully treated by vaccine, combined with the administration of repeated doses of citric acid. The patient was a girl of seventeen. A pimple was first noticed on the right cheek, which was squeezed but no pus exuded. Two days later she had a hard indurated inflammatory mass about the size of a shilling on the right cheek adjoining the lip. The temperature was 99° F. Soon the upper lip on the right side began to swell and pus discharged by many small holes from its under surface and the lower lip began to swell. Soon the whole of the right cheek was dusky in color, with an indurated swelling extending upward from the lip, the eye being nearly closed and the groove on the side of the nose nearly obliterated. She was almost unable to open her mouth, there were sordes on the teeth, and her tongue was very foul. There was no fluctuation present. The temperature was 103° F., the pulse 140; the patient was somewhat drowsy, semi-delerious, and evidently very ill. A dose of 50,000,000 staphylococci (mixed stock vaccine) was inoculated. The next day there was not much change. On the day following a culture taken from the pustule of the lip gave a pure growth of *Staphylococcus aureus* from which a vaccine was prepared and a dose of 25,000,000 staphylococci were administered. In three days improvement was noticed. Later another injection of the patient's own staphylococci were given. The blood withdrawn clotted almost immediately and, therefore, one-dram doses of citric acid were administered every four hours for four doses. The patient made an uneventful recovery, the only sign of illness left being a dimple on the left cheek caused by the skin becoming attached to the mucous membrane of the cheek just over the opening of Stenson's duct.

A Case of Acute Lupus Erythematosus.—J. E. R. McDonagh reports such a case occurring in a female, aged fifteen, who was admitted to the hospital March 12, 1907. She first noticed her hands gradually becoming blue and numb. A few weeks later the feet likewise became affected. For some years previously she had suffered from chilblains. On admission to the hospital the fingers and toes were bluish, showed old scars, and were cold to the touch. There were some blotchy red patches on the face. The nose and ears were normal. A few days after admission a red rash appeared all over the face and on both wrists extending up to the forearms, being accompanied by a persistently raised temperature. No hemoglobinuria was found. On March 26, the face became much worse, the nose appeared cyanosed, and albumin appeared in the urine. On April 3, the nose became very sore and swollen, also the upper lip, and the patient breathed almost entirely through the mouth. On April 12 the face, the hands, and the feet were better, but patches of erythema appeared on the arms and a papular eruption on the back. On April 23 the face was diffusely pigmented and erythematous; it was covered all over with scales, some of which came off easily, others being adherent; the latter on removal had those processes of horny tissue which fitted into small depressions on the skin, and which are typical of lupus erythematosus. On having the hair cut short typical plugs and scarring were found. The scalp, like the face, was diffusely pigmented and erythematous. A small papulo-squamous eruption covered the neck and chest. An atrophic condition of the skin had spread up the back of the hands to about the middle, where the scarring was less marked, and when present was covered with scales and surrounded by a zone of erythema. As elsewhere, many of the scales on removal possessed the horny processes. Later she was brought to the hospital with all the signs of a general peritonitis, and was operated upon. Later she developed a purulent pericarditis, necessitating a second operation, which was followed by death. The point of great interest in this case is the age of the patient. No history of tuberculosis in this case was obtainable.

British Medical Journal, July 17, 1909.

The Function of the So-Called Motor Area of the Brain.—Sir Victor Horsley reports a case which proves for man what has already been established by experiments on monkeys, namely, that so-called volitional movements are not alone generated from the brain through the "motor" area or precentral gyrus, but must also be subserved by other parts. Further, from what has already been said it is reasonable to assume that, in the absence of the precentral gyrus portion of the arm center, the function of movement is executed by the representation of the upper limb in the gyrus postcentralis from which the fibers descend to the optic thalamus through the internal capsule. In his summary he says: (1) The so-called motor area of the human cortex cerebri is really censorimotor; (2) the gyrus precentralis is in man the seat of representation of (a) slight tactility, (b) topognosis, (c) muscular sense, (d) arthric sense, (e) stereognosis, (f) pain, (g) movement; (3) the gyrus postcentralis is in man part of the arm area in which the censorimotor representation is of the same kind as that in the gyrus precentralis, but in it probably provision for censorial coordination is greater and that for efferent impulses less; (4) the giant pyramids or Betz cells are not essential for the performance of purposive or voluntary movements; (5) purposive or voluntary movements can be performed after complete removal of the corresponding part of the gyrus precentralis.

On the Extremes in Mutability of Symptoms in Disseminate Sclerosis.—J. Dixon Mann says it is many years since Buzzard directed attention to the fact that of all organic diseases of the nervous system disseminate sclerosis is the most likely to be mistaken for hysteria. Since then this axiom has received ample corroboration. Although not limited to the early stages of the disease, the difficulties in the way of diagnosis may then be especially perplexing; frequently the indications are vague and only seem to hint at the presence of some indefinite disorder of the nervous system. Absence of characteristic indications, however, by no means constitutes the only difficulty; well-defined symptoms may appear, but they may be abrupt in their onset, erratic in their course, and transient in their duration. They may replace each other with bewildering inconstancy, and after a time may subside and give rise to the impression that manifestations so evanescent are inconsistent with the presence of organic disease. It is with the object of illustrating on the one hand the extraordinary rapid permutations which may occur in the course of distinct indications of organic disease; and on the other, the persistence of such indications for years, followed by their entire subsidence, that he relates in detail the symptoms of two typical cases. In both of them the appearance of several cardinal symptoms removed any difficulty as to diagnosis.

Medicine or Surgery in Early Cases of Cancer.—Skene Keith says that at the present time surgery claims the treatment of all early cases of cancer, and allows an experiment only when it has failed. He asks why, as surgery is not altogether satisfactory, not experiment for two or perhaps even three weeks. All who have much experience with malignant disease know that a certain amount of temporary improvement can be gained in many different ways. If one can show that some definite change is caused by cancer, and that this change can be arrested by treatment, it seems to be reasonably probable that a right line for further investigation has been arrived at. If a careful blood examination were made after every operation for cancer it might, and probably would, show that the cases in which there was no return were those in which the blood was normal or nearly normal, or where it quickly returned to a healthy condition after operation. It is therefore reasonable to advise after all operations for cancer the treatment recommended, or any other which has the effect of materially improving the condition of the blood, even when the actual disease is present. He and his brother have now been working for six years with arsenic, iron, and sodium cinnamate, all old-fashioned cancer remedies. The preparations they have found best are soamin, green citrate of iron and ammonium, and a saturated solution of sodium cinnamate. He reports a case of epithelium of the rectum in which operation was inadvisable. The medical treatment was followed by an apparent cure.

Berliner klinische Wochenschrift, July 5, 1909.

Hemolysis in Paroxysmal Hemoglobinuria.—Hijmans van der Bergh in two cases of paroxysmal hemoglobinuria investigated the phenomenon described by Donath and Landsteiner. This consisted in the occurrence in the blood serum of such cases, during the periods between the attacks of some substance (a specific hemolysin or amboceptor), which at low temperatures, and only at low temperatures, combined with the blood and caused, on again warming, a hemolysis. He attempted to find a reason for this, or the nature of the specific material. His researches are too complex to be summarized, but he considers that the carbon dioxide in the blood may have some influence on the phenomenon.

French and Italian Journals.

Genital Tuberculosis in the Woman.—Ch. Lenormant finds that genital tuberculosis occurs in about three per cent. of all operations for laparotomy for genital conditions. It is rarely primary, and then occurs in cases of genital infection by coitus with a husband affected with genital tuberculosis, the wife having some solution of continuity of the mucous membrane. It may attack any portion of the genital system. It is rare in the vagina and cervix, where there is a pavement epithelium. It is much more frequent in the uterine body, tubes, and peritoneum. The most frequent location is in the tubes, where it is complicated with tuberculous peritonitis, and sometimes ovaritis. In the vagina it is generally ulcerative, or infiltrating. On the cervix it may form vegetations. In the tubes there is a sac containing pus and detritus. Diagnosis from other forms of genital lesions is almost impossible during life. In case of tuberculous peritonitis it is rather curable, especially after an exploratory laparotomy. In general the treatment should be a combination of operative measures with general anti-tuberculous treatment.—*Le Progrès Médicale*, March 27, 1909.

Appendicitis and Adnexitis.—Henri Hartmann describes appendicitis accompanying adnexitis as being conveyed by way of the peritoneum, there being no direct connection between these structures by way of the blood-vessels or lymphatics. In the woman the appendix frequently descends into the pelvis by pressure of the intestines and of the corsets. Diagnosis is somewhat difficult before operation. Pain is generally located lower down in adnexitis than in appendicitis, as is the swelling when one can be detected. The swelling is broader in adnexitis than in appendicitis and lower down. The history of the case is of value. The absence of a history of menstrual troubles and ascending infection is in favor of appendicitis. The picture of peritonitis is more marked in appendicitis, the expression is more anxious, the sensibility of the abdomen and the distension are greater. Temperature is more elevated and the condition is progressive, while after a time in adnexitis it is regressive. Treatment demands immediate operation as soon as a diagnosis is arrived at.—*Annales de Gynécologie et d'Obstétriques*, February and March, 1909.

Pathogenesis of Some Cases of Cirrhosis of the Liver, with Special Reference to Hepatic Alterations in Pick's Disease.—Alfredo Baduel, from his study of cases and experiments on animals with reference to the cause of cirrhosis of the liver, concludes that there are cirrhoses due to venous, arterial, and biliary causes, but also those of lymphatic origin. A slow, chronic peritonitis is of great importance in this type of cirrhosis. The products of inflammation in the peritoneum following the lymphatics, especially the perivenous vessels, may reach the internal portions of the liver and cause cirrhosis. Experimentally we can demonstrate direct channels of communication between the peritoneal cavity and the central portion of the liver. The abundance of these vessels in the superficial portion of the liver cause the frequent capsulitis that may be observed in livers in which the parenchyma is little affected. Alterations of the liver in Pick's disease cannot be ascribed solely to stasis. For the production of the ascites and the intra- and perilobular connective tissue increase peritonitis must be the active agent, the active agent being carried by the lymphatic current. *Il Policlinico*, April, 1909.

Tuberculosis and Pregnancy.—V. Bre[illegible] says that in tuberculosis with pregnancy the prognosis for the mother is generally bad. After labor there is pretty sure to be a renewal of the bacillary process. The infant is generally born healthy, but should not be nursed by its mother. *Le Nord Médical.*

Book Reviews.

Il Ricambio Materiale nelle Anemie Gravi. Par Dott. G. Padoa, Della Clinica Medica Generale del R. Instituto di Studii Superiori di Firenze, diretta dal Prof. Pietro Grocco. Milano: Società Editrice Libraria, 1909.

The great interest now evinced in the study of the chemical relations between the intake and output of the body has resulted in the establishment of a certain number of facts as regards the metabolism of normal human beings, but only as the result of an extraordinary amount of research. Much more complicated from a chemical point of view are the conditions which occur when the human body is the site of some pathological change. This monograph is devoted to the careful quantitative determination of the metabolism of a number of persons suffering from severe anemia. After a thorough historical introduction and a section on technique, the writer considers his own eight investigated cases, giving the histories and presenting in tabular form the various figures obtained. The results seem microscopic as compared to the enormous amount of labor which must have been expended in carrying out the routine of the analytical methods; yet just such careful, thorough papers are of the utmost importance in furnishing the fundamental facts upon which the chemical pathology of the future must be built. The general typography of the monograph is worthy of mention; the print is extremely clear and large, and the extensive bibliography is remarkably free from those errors in spelling proper names which disfigure so much of the writings of the French laboratories.

Über die Wirkungsweise der Gaumen- und Schlundmuskulatur bei angeborener Gaumenspalte. Von Hofrat Dr. med. C. Röse. Berlin, Verlag von Julius Springer, 1909.

This pamphlet is a reprint from the *Deutsche Monatsschrift für Zahnheilkunde*, in which attention is directed to the necessity of cooperation between the surgeon and dentist in treating cases of cleft palate. Often although the operation itself is a success, the child is unable to articulate properly because the soft palate is too short. It becomes necessary to substitute an obturator, and the form best adapted for the purpose seems to be that devised by Sürsen because this most closely simulates the action of the soft palate.

Atlas and Epitome of Ophthalmoscopy and Ophthalmoscopic Diagnosis. By Professor Dr. O. Haab of Zurich. Edited, with additions, by George E. de Schweinitz, M.D., Professor of Ophthalmology, University of Pennsylvania. Second Revised Edition. Philadelphia and London: W. B. Saunders Company, 1909.

The second American edition of Haab's Atlas of Ophthalmoscopy is an excellent work for all students of ophthalmology, as well as for those who are interested in the subject. It is of convenient size, well printed, and the chromolithographic plates are very good representations of the conditions depicted. The first part of the work is devoted to a description of the technique of ophthalmoscopy in all of its phases. Then follow the colored plates. A description of each plate is found on the page opposite to the plate. There are a number of colored plates illustrating the pathology of many of the diseases of the retina and choroid. These are fully described. The work is quite complete.

Appendicitis and Other Diseases of the Vermiform Appendix. By Howard Kelly, M.D. With 215 original illustrations, some in colors, and three lithographic plates. Philadelphia and London: J. B. Lippincott Company, 1909.

The appearance of a second edition, within four years, of such a complete work on appendicitis is in itself its best recommendation. The author has attempted to make this edition of more practical value to the general surgeon, yet it should be read by every one who is to-day practising medicine. The chapters on clinical history, leucocytosis, and treatment before and after operation will prove of great value to the practitioner who never touches the scalpel.

The first chapter contains a history of this disease and well shows the great part played by the American surgeons in clearing up the real nature of the many conditions formerly grouped under the term "idiopathic peritonitis." The anatomy and pathology of the appendix and the different locations of the organ in the abdomen are made clear by numerous illustrations and by diagrams picturing the embryological development. Kelly then discusses fully the bacteriology and etiology of appendicitis, and suggests that the repeated occurrence of the disease in families may be due to anatomical peculiarities or a constitutional predisposition, and that traumatism is more often an exciting cause than is generally supposed. He considers that the ideal time for operation is early, within the first twenty-four hours; the presence of pus indicating a mistake on the part of the patient, the physician, or the surgeon. In the chapter on Appendicitis and Typhoid Fever, however, Kelly points out the fact that the "typhoid appendix" requires operation but rarely.

The chapter on Treatment Previous to Operation is addressed particularly to the practitioner who has no surgeon at hand, yet a list of aphorisms contained in it should appeal to the surgeon as well. One of the most imperative of them is "Never give purgatives in appendicitis!" Operative treatment is copiously illustrated, minute details of both simple and complicated operations being fully pictured. Drainage is discussed in the chapter on abscess near the appendix; the author's practice is to drain the entire septic area through a large opening with a loosely rolled drain. The final chapters contain a thorough review of the literature of neoplasms and specific infections of the appendix and a discussion of the medicolegal aspects of appendicitis.

Refraction and How to Refract. Including Sections on Optics, Retinoscopy, the Fitting of Glasses and Spectacles, etc. By James Thorington, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic anl College for Graduates in Medicine; Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia, etc. Fourth Edition. Philadelphia: P. Blakiston's Son & Co., 1909.

In the fourth edition this popular work has been thoroughly revised and some additions have been made to the text. The subject is treated in as simple a manner as possible compatible with thoroughness. Abstruse formulæ are omitted. It has apparently been the object of the author to produce a work which would present the practical part of refraction in a form that would be readily understood by the student, even if his knowledge of mathematics is limited. The subject is fully covered and the teachings are trustworthy.

Uber die Entstehung und Verbreitung der Tuberkulose im weiblichen Genitaltrakte. Von Dr. Albert Blau, Assistenten der Klinik von Rosthorn in Wien. Berlin: Verlag von S. Karger, 1909.

This pamphlet contains the results of the author's observations on the method of infection of the female genital tract with tuberculosis, both in animals and in the human subject. A careful examination of thirty-six women afflicted with this disease showed that in no instance could the primary infection be traced to the genital tract, nor could any ascending infection be demonstrated. He also found that in guinea-pigs, which are particularly susceptible, the injection of even a highly virulent culture of tuberculous material was incapable of producing the disease unless certain predisposing factors were at hand, such as the puerperal state or injuries. It would appear, therefore, that the same condition must be present in the human subject, as otherwise the development of the bacilli is inhibited by the character of the secretions, and their penetration is prevented by the dense epithelium which covers the vaginal walls and the cervix. The presentation in detail of the cases on which these observations are based is very convincing, and the work forms a very valuable addition to the literature of the subject.

General Surgery. Volume II of the Practical Medicine Series. Edited by John B. Murphy, A.M., M.D., LL.D.; Professor of Surgery in the Northwestern University; Attending Surgeon and Chief of Staff of Mercy Hospital, Wesley Hospital, St. Joseph's Hospital, and Columbus Hospital; Consulting Surgeon to Cook County Hospital and Alexian Brothers Hospital, Chicago, Ill. Chicago: The Year-Book Publishers, 1909.

Practically the whole realm of general surgery is covered in this book. Among the subjects considered are the surgery of the Skull and Brain, esophagus, Thorax, and spine, Matas' operation for the radical cure of aneurysm, and the transplantation of bones and joints. Under the heading of abdominal surgery are considered postoperative phlebitis, parotitis, and occlusion, peritonitis, the surgery of the mesentery, Omentum, and Stomach. Due space is given to intestinal surgery, the surgery of the liver, gall-bladder, pancreas, spleen, kidney, and bladder. Except for a few typographical errors, the book is well written, the subject matter being presented in a concise and readable manner.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held June 15, 1909.

Dr. J. M. Van Cott in the Chair.

Some Facts Regarding Brooklyn's Summer Infant Mortality.—Dr. Louis C. Ager of Brooklyn read this paper. He said that there were two classes of facts that one had to consider, namely, infant mortality in general, and the relative infant mortality of Manhattan and Brooklyn. The latter borough compared favorably with the average city having the same climatic conditions. In the older portion of New York City, out of a total mortality of 74,000, there was a mortality of 24,000 in children under five years. One-fourth of these were for diarrheal diseases and 2,000 deaths were from measles, scarlet fever, and diphtheria. Thus diarrhea claimed three times as many deaths below five years as from the above three contagious diseases at all ages. Ninety per cent. of the deaths were in children during the first and second years of life. In the chart by weeks the deaths from diarrhea were insignificant until the first and second weeks in June; they then jumped to twice as much. The average of 15 deaths per week in January, February, and March rose to 170 to 180 per week. In all parts of the city there had been a reduction in the summer infant mortality from year to year. This was to be attributed to the beneficent activity of the various relief agencies working against this condition. At the present time the foreign-born population was more difficult to assimulate than twenty-five years ago. The next set of facts that Brooklynites were particularly interested in were those that related to the comparative infant mortality of Manhattan and Brooklyn. The ratio of the population of the former to the latter was as three is to two. Brooklyn had a better class of people in the tenements than Manhattan. In Brooklyn it was much easier to get out of the extremely congested districts. While Manhattan had more of the big double-decker tenement houses of the older type, yet Brooklyn had more of the old converted private houses which were worse from a sanitary viewpoint, their floors, walls, and plumbing being much inferior. In Brooklyn, the general death rate had a better showing. In 1907 the death rate of Manhattan was 18.51, while that of Brooklyn was 17.98. Yet the infantile death rate of Brooklyn was heavier. In 1903 there was an excess of 0.1 per cent. in the deaths of infants under one year over those in Manhattan. In 1907 this excess had increased to 1.1 per cent. If the infantile mortality of Brooklyn had been the same as that of Manhattan there would have been 300 less deaths in the former borough during 1907. A study of the diarrheal diseases during 1908 showed similarly marked differences. This was an exceptionally favorable year. Although the mortality jumped high, it fell more quickly than in other years. Even in Manhattan, during July, there were regressions: the mortality in the second week was lower than in the first. In Brooklyn, on the other hand, the mortality jumped higher and higher each week, rising from 15 to 173 in the course of one week. Another important set of facts bearing upon this question was that Brooklyn had neither the funds nor the relief agencies that were at the disposal of Manhattan. There were a large number of foci directed against the infantile mortality of Manhattan. In the latter there were as many as 144 fresh air agencies. These took care of 31,000 children as against 6,000 taken care of in Brooklyn. In Manhattan 100,000 children were given outings in day parties, as against 10,000 in Brooklyn. In Manhattan there were 55 day nurseries, as against 13 in Brooklyn. There were three milk distributing agencies in Manhattan, and there was but one in Brooklyn. In Manhattan, the number of babies fed the whole year was 2,800, while in Brooklyn the number was nil, but during the summer months 2,200 infants were provided with milk. The total number of daily feedings provided was 280,000 in Manhattan, as against 20,000 in Brooklyn. In Manhattan there were 28 child's nurses, while in Brooklyn there were 2. In Manhattan there were 160 general nurses, while in Brooklyn there were 20. In the former there were 80 dispensaries, while in the latter there were 17. Although the amount of free dispensary work was overdone in Manhattan, yet there was little doubt that this, together with the superiority in the extent of infant relief work, accounted for Manhattan's advantage over Brooklyn, so far as the infantile death rate was concerned.

Predisposing Causes and Prevention of Summer Diarrhea.—Dr. John W. Parrish of Brooklyn read this paper. He commented on the high mortality of summer diarrhea. Every influence that diminished the vitality of the infant either during intrauterine life or later contributed toward the maintenance of this high mortality. Syphilis, alcoholism, and a defective nervous system in the parents tended to impair the powers of resistance in the child. The presence of general tuberculosis, syphilis, rachitis, and diseases of special organs in the child made the latter more prone to the severe invasion of summer diarrhea. A fatal outcome in summer diarrhea did not usually occur in children that had been previously healthy. These were, of course, frequently the victims of cholera infantum, which was a different and at present much rarer affection. Some cases of ileocolitis were exceptionally severe. As a rule there was a condition of malnutrition preceding the fatal illness. This malnutrition was due to disease, bad air, or inefficient feeding. If the child was bottle-fed the food was frequently bad, either because it was too weak to nourish the infant, or too strong, or poorly adapted to the child. Not five per cent. of the deaths due to diarrhea occurred in previously healthy children. Chronic digestive troubles frequently antedated the fatal attack. It was noted that many of these cases of chronic indigestion were frequently erroneously attributed to teething. In the prevention of summer diarrhea one had to see that the infant had proper clothing, abundant fresh air, and suitable food. It was a common fault that infants were wrapped in too much clothing. The abdomen and feet were to be kept warm, but it was important to avoid causing excessive perspiring. The necessity of fresh, cool air was alluded to. The baby was frequently kept in the kitchen, while the mother was at work, and sometimes the crib was near a hot stove. The temperature of the nursery was to be 68° during the day and 10° cooler at night. In summer the infant was to be kept in the coolest room in the house. Northrup had advised that the infant ought to be kept in the fresh air 23 hours out of 24, one hour being allowed for changing the infant from room to room. It was important that the infant should get a suitable food. The more universal use of certified milk would have an important influence in checking the prevalence. Next in importance was the devising of simple rules for adjusting the food to the individual infant. Simple directions were to be given the mother. Insistence on maternal nursing, wherever this was possible, was to be the rule. Cow's milk was no substitute for woman's milk It contained twice as much protein and the proportion of casein to lactalbumin was 5 to 1 instead of 5 to 2 as in woman's milk. In both there was the same amount of fats, but they differed in quality. In cow's milk there was 4.5 per cent. milk sugar, while in human milk there was 7 per cent. It was the aim of American pediatrists to furnish the artificially fed infant as close an imitation as possible of mother's milk. Failure in artificial feeding was frequently attributed to casein, and consequently the latter was greatly diminished and the difference made up with

large amounts of fat and sugar. What were frequently interpreted as casein curds really turned out to be of fatty origin. Soltman and Schloss had found that large curds consisted of casein and fat, while small curds consisted mostly of fats. Fishel and Schloss attributed most cases of failure in artificial feeding to excess of fats. This was a common observation. Many cases of infantile wasting were also due to the same cause. The speaker in using modified milk did not employ anything stronger than the top pint, containing 7 per cent. fat. He began the feeding by diluting the whole milk, then the upper two-thirds of the bottle, and then the upper pint. Most babies did not digest whole milk within the first year. The ideal was to begin with a weak food and to gradually accustom the alimentary canal to a stronger one. The more one weakened the food the more one weakened the infant's digestion. The pedagogical principle applied here: to begin with easy tasks and then to gradually increase them. In the event of failure daily lavage and outdoor air were valuable. If these failed then it was necessary to feed with whey and cream. In this manner one altered the relative proportion of fat and casein so as to more closely resemble that of human milk. A simple measure was the use of skimmed milk. Sometimes buttermilk agreed. In some cases the use of condensed milk in the proportion of 1 in 24 parts of boiled water was of value, while in some cases cereal dilutions proved eminently useful. It was important to give the mother definite instruction in the care of the infant. During past years this was neglected. The inauguration of a system of instruction by visiting nurses was a recent step in advance. In Brooklyn little had been done in this line. There was one visiting nurse in South Brooklyn and one in connection with St. Christopher's Hospital. It was desirable that there should be one such nurse in each dispensary. The gospel of clean milk was to be taught. The milk had to be kept in the refrigerator below 50° F. Pasteurization was necessary in summer. The importance of fresh air was emphasized.

The Hygienic and Dietetic Treatment.—Dr. Le Grand Kerr of Brooklyn read this paper. He said that the question of age incidence was within the realm of his paper. The incidence of attack was very small under the age of three months, but from this period there was a very rapid increase until the age of two years, and that the greatest mortality was during the last nine months of the first year of life. This was synchronous with the period during which the hygienic and dietetic care of the infant was most difficult. In the hygienic and dietetic care of these cases one had to consider the relative importance of the four chief etiological factors, namely, the soil, the season, the food, and bacterial infection. Other factors were density of population upon an unclean soil, insufficient sunshine, defective ventilation, maternal neglect, and contaminated food. The influence of the soil was an important one. A loose and particularly a loose and polluted soil was one upon which infantile diarrheal mortality was apt to be high. This was one of the important, if not one of the chief, reasons why the infantile diarrheal mortality was less in the Borough of Manhattan than in the four other boroughs—Manhattan Island was nearly all rock; this favors the prompt and efficient removal of sewerage. This latter fact gave Manhattan another advantage. A deficient rainfall during the summer favored the increase of diarrheal disease. There was a diversity of opinion as to the relation between the temperature and diarrhea. The opinion as to the depressing effect of the temperature was untenable in view of the health of infants in tropical climates and in view of the fact that infants under three months were practically immune from any except the most virulent infection. The "miasm" theory was controverted by the fact that summer diarrhea was largely a disease of cities whose soil was sealed by concreted streets. The following facts showed that the disease was due to a contaminated food and particularly a fluid food: The disease affected the alimentary system mainly. It was not due to trauma. It was in no sense a constitutional disease. It was an infection of the alimentary canal and was most prevalent during the first two years of life. A prolonged high temperature favored the growth of infective bacteria and processes of decomposition, particularly in milk, which was the chief pabulum of infants. The prolonged high temperature also favored the collection and dissemination of dust with its bacteria and also the increased propagation of flies which was coincident with the increase in summer infantile diarrhea. The direct hygienic treatment involved the removal of the infant from the city as soon as practicable, preferably to the seashore, and kept there for a considerable time—as the dangers of relapse were great. Enforced rest in the open air day and night was desirable. The clothing was to be light and loose. For the restlessness and fever, and for cleanliness, the use of water externally was important. For the reduction of temperature the tub bath at 100° Fahrenheit was to be used, with the addition of iced water, until the temperature of the bath was 85° F. Disinfection of the napkins was necessary. Excoriations were to be prevented. The direct dietetic treatment involved the withholding of all food during the first twenty-four hours. To allay hunger and thirst it was permissible to give frequently small amounts of sterilized water, thin barley water or cold whey made without beating the curd. In the last procedure the fat was below one per cent. while vigorous beating of the curd liberated as much as three per cent. of the fat. Albumin water was not to be given, as it readily underwent decomposition. If the above were vomited, absolute withdrawal of the food was essential. With improvement of conditions the infant was allowed the breast after forty-eight hours, with the restriction that nursing was to be alternate and for not over three minutes. In artificially fed infants the food was to be withheld for a longer period and in addition to the substitutes mentioned in the case of breast-fed infants, there could be used the farinaceous or malted foods without milk bouillons and the dextricized cereals. Return to the usual food was to be gradual and slow. Relapses were common and sometimes fatal within twenty-four hours. Infantile diarrheal mortality was a social as well as a medical problem, and much of it was concerned with maternal care. Carelessness and ignorance were potent factors in the morbidity and mortality of the infantile period. Breast milk had no perfect substitute. The nursing mother was to be instructed as to how to nurse her babe correctly. There were three avenues of instruction: (1) the direct instruction of mothers in the care and management of infants; (2) the follow-up system of female visitors in the care and management of infants; (3) the education of girls in domestic hygiene. Present commercial and economic conditions compelled the employment of married women. This employment was to be controlled in such a manner that a limit was to be placed upon the time before and after confinement that a woman was allowed to work. The infant's care was to be safeguarded during the absence of the mother through the agency of day nurseries. Scrupulous care to prevent overfeeding, too frequent feeding, and a formula to adapt a suitable and uncontaminated food to the infant's needs was necessary. In the presence of high temperature the food of the breast fed as well as the artificially fed was to be reduced. In the former this was accomplished by giving an ounce or two of sterile water immediately before the nursing and in the bottle fed by adding water to the food. Every diarrhea in an infant occurring during the months of June, July, and August was to be treated as the possible beginning of a fatal disease. Anything short of this was neglect.

The Medicinal and Mechanical Treatment of Summer Diarrhea.—Dr. Archibald D. Smith of Brooklyn read this paper. He said that the indiscriminate use of drugs was harmful. The general principles of the treatment were the same for all cases. They included rest in bed and stimulation, the emptying of the stomach and intestines, the administration of fluids, the elimination of toxins, the allaying of the inflammation, and the treatment of special symptoms. Food was to be withheld for from 8 to 24 hours. Boiled water was to be given frequently. It was important to empty the stomach and intestines. The initial vomiting frequently sufficed for the former, or a single washing was all that was necessary. In severe cases of cholera infantum the stomach was always to be washed. For this purpose 9 to 10 inches of a catheter was to be introduced, and the stomach washed with a quart of water at 100° F. In a child over two years of age the struggling that attended the stomach washing was undesirable, in which case this was obviated by the administration of plenty of boiled water and then inducing vomiting. The intestines were to be emptied with calomel in doses of ⅛ to ¼ grain every hour until the characteristic stool occurred. Castor oil was followed in four to six hours with a sweeping catharsis. If the movements were small in amount, saline catharsis was of value, but was not to be employed in cases with depressed fontanelle. Sodium sulphate in small doses of 10 grains each in one dram of water were to be given. On the first day two or three colon irrigations were to be given, with normal saline at 100°, the bag at first 2 feet above the child and later 4 or 5 feet. One-half a gallon of saline was to be used for a single irrigation. The colon in a child two years old held 2 to 3 pints. In collapse, saline at 110° F. was to be used. Where there was a high temperature the fluid was to be at 80°. The patient was to be given plenty of cool boiled water. In the most severe cases the only effective method of treatment was hypodermoclysis; 8 to 12 ounces of normal saline was to be slowly introduced, within 24 hours, into the loose cellular tissue of the abdomen or buttock. For the elimination of toxins, the catharsis and other treatment sufficed. To allay the inflammation it was necessary to cover the inflamed mucous membrane; this was accomplished with bismuth subnitrate, one to two drams per day in a child one year old. Besides, it was antiseptic, inhibited the growth of bacteria, and controlled vomiting. Opium was too frequently used, and used at the wrong time. Its best use was in the convalescent stage, in the form of paregoric, in doses of five minims to a child of one year. In cholera infantum, with collapse, morphine in doses of 1/100 grain was to be given hypodermically. Special symptoms called for treatment. For prostration whiskey was valuable; its maximum dose was one-half an ounce within twenty-four hours to a child one year old. Tincture of strophanthus was also useful. Strychnine was not to be used where there was a tendency to convulsions. For fever, tub baths, cold water rectal injections, and cold packs were indicated. The speaker next discussed the antitoxin treatment of summer diarrhea. The antidysenteric serum was used only in infection with the true Shiga bacillus. In 270 out of 412 cases of diarrhea in children the Flexner or acid type of bacillus was found. This organism did not produce a soluble toxin, hence no antitoxin for this form of infection could be found. It was impossible to distinguish clinically the two types of infection.

Dr. Henry N. Read of Brooklyn said that it was important to make a bacteriological examination in many cases of summer diarrhea, in order to single out those that could be appropriately treated with the antitoxin. The Japanese had reduced the mortality from summer diarrhea very much by means of this mode of treatment. He extolled the value of the continued use of hypodermoclysis in the bad cases. By this measure many lives had been saved.

Dr. Elias H. Bartley of Brooklyn said that twenty-five years ago cholera infantum was a very common and very fatal disease. It was then that the milk bottle came into use, and this, together with other improved methods in handling the milk, had made cholera infantum comparatively rare. He emphasized the fact that had already been brought out, namely, that summer diarrhea killed off a large number of previously feeble children, including those that had been illegitimately or prematurely born. One of the causes of summer diarrhea was the depressing effect of the atmospheric heat upon the sympathetic nervous system of the child, and also in diminishing its vital resistance. The infection was frequently carried by flies. The speaker had observed cases of salol and bismuth poisoning in infants. Irrigation of the colon was valuable in collapse. He had found good results from the use of small doses of resorcin.

Dr. William A. Northridge of Brooklyn said that some cases demanded colon irrigation as frequently as every three hours. He had employed lavage of the stomach in some cases every day, and even as frequently as three times a day. It had been the practice of physicians to send cases too late to the seaside hospital. One point in the treatment had not been mentioned, namely, the use of nutrient enemata of half an ounce of peptonized milk, in white of egg. During the first twenty-four hours it was important to go without all food, giving only sterile water, or possibly a weak whey mixture. Following this the use of a condensed milk mixture, consisting of one part of condensed milk in twenty-four parts of water, often checked diarrhea. This mixture could be strengthened from day to day and the case tided along to the use of certified milk properly diluted. It was the tendency of the best medical practice to abandon the routine use of drugs in the treatment of summer diarrhea. Preparations of opium were to be administered by the physician himself whenever necessary.

Dr. Sigmund Beck of Brooklyn in discussing the seaside treatment of summer diarrhea said that the ideal mode of furnishing the advantages of lower solar temperature was that afforded by the floating hospitals. He thought that, if these were increased in number, the mortality from summer diarrhea would be materially diminished.

THE AMERICAN THERAPEUTIC SOCIETY.

Tenth Annual Meeting, Held at New Haven, Conn., May 6, 7, and 8, 1909.

F. H. Gerrish, M.D., of Portland, Me., President, in the Chair.

(*Continued from page 207.*)

Diet as a Prophylactic and Therapeutic Agent.—This paper, prepared by Dr. H. W. Wiley of Washington, D. C., was read by Dr. F. P. Morgan. There was, the author said, an increasing belief in the medical profession, and this was founded on substantial evidence, that diet was an important factor in the production and cure of disease. A perfectly healthy, well-nourished organ would become infected with any disease germ with great difficulty. In other words, it was self-protective, and, this being granted, it was evident that food must play an important part in the prevention of disease. It followed, then, as a necessary condition, that the debasement of the diet, the addition of injurious substances to, or the abstraction of valuable ingredients from, articles of food, diminished the power of that diet to maintain the body in a state of hygienic equilibrium. Hence the first conclusion regarding food as a prophylactic was that it should be of a proper quality. The second was that it

should be of proper quantity—neither too small nor too large for the requirements of the system. The sum of nutrition was the normal injection of all the necessary ingredients of food for man, protein, fat, starch, etc., in their appropriate proportions. It had been contended that the ordinary diet, especially in the United States, contained too large a proportion of protein, but the health of the people would certainly suffer if this were reduced too much; and so of the other elements. In regard to mastication he said that all admitted the desirability of this, both as a mechanical necessity preliminary to deglutition and as a preliminary to the proper mechanical state of food for the first steps of hydrolysis in the process of digestion. This having been accomplished, however, the question might arise whether or not the carrying of this process to excess might not result, first, in diminishing the actual quantity of food necessary, and, second, in actually interfering with the process of digestion. As to the therapeutic usefulness of food, every physician recognized the necessity of sustaining to the utmost the vegetative functions of the body in disease. Excessive production of tissue, especially adipose tissue, was in some respects just as much a disease as the loss which we usually associated with most diseases, and in his opinion the disease which resulted in hypertrophy might as a rule be entirely controlled by diminishing the amount of the diet, unless it had gone so far as to be practically irremediable. On the other hand, the waste of tissue which was the attendant of many diseases often became so great as to threaten life. To combat this condition and stimulate anabolism, food of a proper kind was one of the most valuable of the resources of the physician. In disease, however, the use of food was regulated by entirely different conditions than in health. The first requisite was that the food should be pure, and Dr. Wiley considered that the introduction of any drug of any description into foods intended for invalids was not only undesirable, but criminal. In closing he said that, in his opinion, the near future would see the professorship of dietetics in a medical school advanced to the same rank as that of medicine, and, furthermore, the practice of medicine in the future would be largely a practice of dietetics.

Diet and Care of the Bowels in Typhoid Fever.—Dr. M. H. Fussell of Philadelphia said that until within the last fifteen years the diet in typhoid was liquid, with milk as a basis. Since then, however, a diet much more varied had been recommended by various authorities. The comfort of the patient was unquestionably greater when he was given other food than milk and water. The metabolism experiments of Puritz, in which typhoid patients were fed on meat, bread, milk, eggs, tea, coffee, and port wine, showed that 79 to 82 per cent. of the nitrogen consumed was assimilated. The claim, however, that milk, as compared with solid foods, caused a good culture medium in the bowel was not well founded. Statistics published by Kinnicutt went to show that the intestinal accidents, perforation and hemorrhage, were slightly less when a free diet was allowed than in patients on a milk diet. Aside from this, the tympany and diarrhea which some writers attributed to milk diet existed more in the imagination than in reality. To help us to judge of the effect of a liberal and a milk diet, respectively, upon accidents, relapse, and mortality, Kinnicutt had given some remarkable statistics collected from different hospitals, and the speaker had another series to present from St. Timothy's Hospital in Philadelphia. The figures were slightly in favor of the liberal diet, but the differences shown were certainly negligible. The foolhardiness of using any diet in typhoid except under strict watchfulness was evident, and any physician of experience would be certain, without statistics, that gross errors in diet caused both relapses and intestinal accidents. In hemorrhage all food must be withdrawn for a time, though water might be given in small quantities. Thromboses were said to be much less frequent in patients who were well fed, and he believed that there was such a thing as fever of malnutrition following a liquid diet. His own advice as to diet for typhoid patients was to study each patient well, and feed him according to his needs. The patient first should be put on a liquid diet, with milk and egg albumin as a basis. The diet should be increased up to a limit of 2,500 calories by the addition of starches, minced chicken, or meat, chopped soft parts of oysters, and soups, after the dietary of Shattuck. A careful watch should be kept upon the stools and digestive functions, to see that neither undigested curds nor other particles passed, and that tympany, diarrhea, or constipation did not occur. The safe course was to give divided doses of calomel if the patient was seen in the first week, and after that to see that a daily evacuation was secured by a glycerin or a simple enema, if there was a tendency to constipation. If diarrhea occurred food should be stopped or regulated, and if it then persisted, a mixture of salol and bismuth should be given, or an opiate if the looseness was excessive. To conclude: Clinical and autopsy evidence proved that a regulated milk diet did not irritate the bowel; neither did a diet of milk reinforced by carefully selected carbohydrate and nitrogenous diet other than milk. Common sense must be applied to both, and both might be used; but in semi-unconscious or unconscious patients the diet was perforce liquid.

Dr. James C. Wilson of Philadelphia said that in typhoid fever the great point was to individualize the cases as far as possible, and treat each patient according to the special conditions present. It was often his practice to give a cup of coffee, more or less diluted with milk, in the morning, and then every two hours afterward milk in some form. He regarded it as very important that the quantity should be moderate and that it should be taken very slowly. Various preparations might be employed from time to time, such as junket, kumyss, custard, and ice cream. In some cases bread might be given, but he had never felt it desirable to allow chicken, chops, or beefsteak. His position, he believed was somewhere between the "liquid diet" and the "liberal diet," sometimes a little more in the direction of one and sometimes the other. He was of the opinion that the rapid emaciation met with in typhoid was a matter not of diet, but a condition due to the infection of the whole system.

Symposium on Psychotherapy.—The Psychological Principles and Field of Psychotherapy.—Dr. Morton Prince of Boston first stated certain accepted facts of observation, and then called attention to certain principles governing the functioning of the nervous system, as (1) complex formation. By this was meant that associated ideas, feelings, emotions, sensations, movements, visceral functions of whatever kind, tended, after constant repetition or when accompanied by strong emotion, as well as under other conditions, to become linked together into a system or group in such fashion that the stimulation of one element in the group stimulated the activity of the rest. Such a group was commonly called a complex. The linking of functioning might be almost entirely of ideas or of physiological processes, or of both. The pathbreaking demonstrations of Pawlow furnished the key to the mechanism of many neuroses and psychoses, for, indeed, the educated reactions of the gastric and salivary glands to ordinarily indifferent stimuli from the environment and to psychological states were in reality nothing but an artificially created psycho-neurosis, a perversion of the normal reactions. Such artificial synchomes rendered comprehensible such neuroses as the neurotic type of hay fever, which belonged to the association neuroses. The speaker then explained in some detail the principle of

education in the formation of the neuroses and psychoses. (2) Conservation; by which was meant that all experiences —anything that had been thought, heard, seen, or felt— tended to be conserved in the nervous system in such a way that they could be reproduced in a form approaching that of the original experience. This was the basis of memory. Conservation was fundamental for education, and upon it the law of the linking of complexes depended. (3) Dissociation; which governs the normal psychonervous mechanism and was observed in a highly marked form in pathological conditions. Hysterical amnesia, paralysis, and anesthesia, as well as the normal phenomena of forgetfulness, absentmindedness, moods, etc., were forms of dissociation. Subconscious ideas were likewise dissociated ideas. (4) Automatism; which played a part in both normal and abnormal life. Habit actions and absentminded acts depended upon this mechanism. Pathological fixed ideas, hallucinations, tics, spasms, etc., might be automatisms of a sensory or motor variety. (5) Emotional energy. Intense sthenic emotions and feelings were accompanied by an increase of the vital functions, while, on the other hand, certain depressive emotions and feelings were accompanied by a decrease of the vital functions. All these principles or tendencies in the functioning of the nervous system, he said, were made use of in psychotherapy, which was educational in principle. What we tried to do was to resynthesize the dissociated personality, form new, healthy complexes, and organize them so intensely that they became a part of the organism and automatic. Complexes with a strong emotional energy were selected as tending to bring about healthy syntheses and revitalize, as it were, the individual. Finally, the methods of applying these principles in different diseased conditions, such as neurasthenia, hysteria, etc., were described.

Psycho-Analysis in Psychotherapy.—Dr. Ernest Jones of Toronto said that in psychotherapy most of the medical world was at present only entering on the first stage, in which it was recognized that we had secured a new therapeutic weapon of the utmost value, the capacity to alleviate certain complaints by purely mental measures—in other words, psychotherapy in its broadest sense. Psychoanalysis represented the second stage in the evolution of psychotherapy. Here a deeper insight was sought into the essential nature and origin of the morbid phenomena, with a view to obtaining a fuller understanding of the aims of treatment, and so to achieving greater precision in its application. Freud's psychoanalytic method was based on the knowledge that the symptoms present in the psychoneuroses owed their origin to a conflict between two groups of ideas which could not be brought into harmony with each other. One complex of mental processes was for some reason of such a kind as to be unacceptable to the main body of the personality. The personality failed to assimilate it, as it were, and the repressed complex then took on an automatic existence, and continued as an irritating foreign body, in the same way as any physical foreign body which had not been absorbed. The central aim of the psychoanalytic method was to enable the patient to discover and appreciate the significance of the mental process manifesting itself as a symptom. In carrying out the method several procedures might be adopted, according to circumstances. Only a very few of those acquainted with this method employed the use of the hypnotic state, as it had certain grave disadvantages. Under special circumstances, however, it had a legitimate place. The procedure developed by Freud was the one most generally adopted, and it gave by far the most satisfactory results. It was one of the ways of obtaining what was known in psychology as free association, and was carried out by getting the patient to concentrate his mind on a given idea, usually one referring to a symptom, and asking him to relate truthfully, in the order of their appearance, the various thoughts which came to his mind. At first he would omit to mention a number of thoughts, on various grounds, but after a time he would acquire the capacity of adopting the noncritical and passive attitude essential to success. There were various other means of reaching buried mental complexes, among which Jung's word reaction association method was of the greatest assistance, particularly in furnishing a series of clues to serve as starting points for future analyses. By means of such methods we were enabled to determine the origin of the symptom by retracing the steps along which its pathogenesis proceeded. It was impossible to deal with the underlying complexes, to discharge their pent-up effect; to render them more assimilable by the patient, unless one succeeded in this task and brought them to the full light of day. The patient would then be able to free his personality from the constraining force of these complexes, and, by taking up an independent attitude toward them, to gain a degree of self control over his aberrant thoughts and wishes which was previously impossible. The method was thus in almost every respect the reverse of treatment by suggestion. In the latter the physician added something to the patient's mind: confidence, belief, etc., and thus made the patient more dependent on him. On the other hand, the psychoanalytic method took away something, namely, inhibition, and enabled the patient to develop a greater measure of self reliance and will power, as well as to acquire an understanding of his own mind, which was of the greatest possible value for future prophylaxis. The training received by the patient was thus an educative one in the highest sense of the word. The conditions which lent themselves to psychoanalytic treatment comprised practically all forms of psychoneuroses, the different types of hysteria, the phobias, obsessions, anxiety neuroses, and even certain kinds of sexual perversions.

Simple Explanation as a Therapeutic Method.—The aim of this paper, by Dr. E. W. Taylor of Boston, was to show the possibility of the use of a psychotherapeutic procedure which involved no special technical knowledge and which was available for practitioners in all departments of the profession. It was considered that the procedure was worthy the name of a method, since it worked in practice and was the means of alleviating many distressing conditions which simple encouragement could not accomplish. Its essential feature was the analysis of the mental state with reference to a search for the cause leading up to the developed neurosis. It was pointed out that many conditions regarded in this developed form as indications of an abnormal nervous system were in reality the normal reactions of a sound nervous system under special conditions of stress or misinterpretation of various events, in themselves innocuous. In the attempt to treat such cases the following general principles were suggested. (1) After eliminating or properly estimating physical causes, the mental attitude of the patient toward his ailment should be carefully determined; in other words, a diagnosis should be made. (2) This was best accomplished by allowing him to tell his complete story, rather than by a primary process of interrogation. (3) Having determined the false point of view almost invariably revealed which had led up to the neurosis, the attempt was made to explain why such a series of events as that disclosed would be likely to lead to this result. (4) The patient having been impressed with the correctness of the physician's point of view, the process of readjustment, or, to use the more popular but possibly too comprehensive term, his reeducation began. (5) This is accomplished by pointing out in a painstaking way the correct way to mental health through a realization on the part of the patient of his misconceptions and an effort toward the establishment of more rational mental adjustments.

The Hypnoidal State, and the Method of Hypnoidization.—Dr. Boris Sidis of Brookline, Mass., said that since hypnosis met with so much opposition, the question naturally arose, Was it possible to affect and modify pathological mental states outside the hypnotic state? In "The Psychology of Suggestion" he had pointed out that suggestibility could be induced also in the normal waking state. He had also shown that, among the conditions of normal and abnormal suggestibility, monotony and limitation of voluntary movements played an important rôle. Any arrangement tending to produce monotony and limitation of voluntary activity brought about a state termed hypnoidal, a subconscious condition in which mental life could be affected with ease. This was essentially a border line state, intermediate between waking and sleep, and also bordering on hypnosis. Like sleep, it had many levels; unlike sleep, however, it rapidly oscillated from level to level. In a series of experiments on sleep which he had published it had been shown that the hypnoidal state was also met with in the lower animals. The conclusion was that this state was the primitive rest state out of which sleep had arisen. In other words, the hypnoidal state was the primordial sleep state. A reversion to this state was of great value in the treatment of many mental disorders. Like sleep, and waking, it was a perfectly normal condition, characteristic of all animal life. Unlike hypnosis, there were no spectacular and sensational manifestations, antagonizing the sober mind and mystifying the patient; it was simply a state of relaxation. The therapeutic value of the hypnoidal state consisted in the liberation of the subconscious reserve energy requisite for the synthesis of the dissociated systems forming the basis of the psychopathic malady. It was highly probable that the therapeutic effects of Weir Mitchell's rest cure and Freud's psychoanalysis were due to the empirical use of the hypnoidal state. This state was also of the utmost value from a purely diagnostic standpoint, inasmuch as it constituted a powerful instrument in the tracing of the origin and development of the psychopathic disorder.

Obsessions and Associated Conditions in So-called Psychasthenia.—Dr. J. E. Donley of Providence, R. I., said that within the compass of psychasthenia should be included only those states of obsession associated, either antecedently, concomitantly, or consequently, with feelings of strangeness, unreality, incompleteness, and depersonalization. If the treatment of psychasthenia was to be fruitful in results, the personality of the physician was of primary importance. He should possess those attributes which were broadly comprised under the name of humanism, and chief among them were psychological imagination, sincerity, and frankness. Given these, there was established the *rapprochement* so essential to any and every therapeutic success. The typical psychasthenic was an individual who found himself burdened with limitations of two kinds, the subjective and objective. Hence, there arose a twofold conflict, the inner and the outer. To modify both these was the purpose of psychotherapy. Among wholly misdirected and fruitless methods of overcoming the obsessions was that of "fighting it out." Instead of this, one should counsel surrender, which was obtained through the process of substitution. The principle underlying the lines of substitution was *ascêsis*, the discipline of the intellect, will, and emotions. In carrying out this *ascêsis* one appealed to the religious consciousness, the use of autosuggestion, esthetic pursuits, the training of attention. The plan of procedure in each case must be minutely individual. There was no royal road in the treatment of psychasthenia; hence the demands made upon the physician's versatility. In many instances much help might be derived from the use of hypnoidization and hypnosis as an accessory to other treatment.

Other papers in this symposium were: **"Psychoprophylaxis in Childhood,"** by Dr. T. A. Williams of Washington, D. C.; **"Character Formation in Relation to Psychotherapy,"** by Dr. J. J. Putnam of Boston, and **"The Psychotherapy of Fatigue States,"** by Dr. G. A. Waterman of Boston.

(To be continued.)

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, May 17, 1909.

The President, Dr. Robert T. Morris, in the Chair.

Asthma and Its Allies.—Dr. Woods Hutchinson, in discussing this subject, said that asthma was one of the unsolved riddles of medicine. Its causation was absolutely wrapped up in mystery; its pathology was in doubt, and the less said about the treatment the better, excepting that each individual case required a special and separate treatment of its own. The statement of our knowledge regarding asthma could be best expressed in the form of negatives. Asthma was not a disease of the lungs, excepting in the sense of producing its symptoms and distress in that region, and causing changes in that part of the anatomy. It was no more a disease of the lungs than was Bright's disease primarily a disease of the kidneys, or cardiac failure a disease of the heart. Though it occurred in the lungs and was attended by shortness of breath, the speaker thought we were safe in saying that it was not primarily nor essentially a disease of the lungs, and that remedies directed to those organs would fail to relieve the condition. In asthmatic attacks there was a spasm of the bronchial muscles analogous to colic in the intestines, but in spite of the apparent severity of the symptoms these patients often do not suffer from true dyspnea, and it would not be strictly correct to say that they were suffering from lack of breath. They are not cyanosed in many instances, and perhaps one-half of them would tell you that instead of their greatest desire being to fill their lungs it was rather to get something out of them. The expiratory rhythm was prolonged at the expense of the inspiratory. In many instances there was apparently not a lack of oxygen, but rather a condition of intense irritation of the bronchial mucous membrane, which the patient was endeavoring to cool off. To look upon asthma solely from the point of view of an actual scarcity of oxygen was to miss the essential factor of the disease. It was rather to be regarded as an exudation of mucus—a so-called bronchial catarrh, accompanied by vasomotor spasm. We had a localized edema of the bronchial mucous membrane, accompanied by an outpouring of mucus, and later perhaps a discharge of leucocytes and cosinophiles, and perhaps even red-blood cells. There was a profuse outpouring of mucus—tough, tenacious, and irritating, which became rolled and twisted into those singular spirals (Curschman's) which were so characteristic of asthma. We had to do with a peculiar reaction of the vasomotor structures in the lungs, and in its grouping asthma was closely allied to urticaria, to hay fever, and the vasomotor disorders of the upper air passages, to colic, particularly the form known as mucous enteritis, to certain of the paroxysmal albuminurias, to several forms of paroxysmal hemoglobinuria, to Raynaud's disease and certain forms of gout and rheumatism, to the "vasomotor ataxias" (so called by Solis-Cohen), and, in its later form, to the lesions of giant urticaria and urticaria pigmentosa. An important and significant feature of asthma was the susceptibility of these patients to some particular thing—in many instances an odor—and one of the most common of these was the smell of a horse. Others could not tolerate the presence of a cat or a Navajoe blanket, and he recalled one man, a freight handler, who always promptly had an attack of asthma when he handled bales of linseed

or cottonseed cakes. Some had an attack when they moved from the city to the suburbs or seaside, or *vice versa*, or even from one room in the house to another. Others, again, traced their attacks to certain articles of food, frequently strawberries or shellfish. In the treatment of asthma a study of each patient individually was necessary, and in the vast majority of cases a careful regulation of the patient's diet and surroundings would insure him at least a considerable degree of relief and comfort. Of medicinal remedies the vasomotor dilators, such as the nitrites and stramonium, the alkaloids of opium, atropin, belladonna, and inhalations of chloroform, gave the largest measure of temporary relief. The most effective remedy in his hands had been found to be suprarenal extract. As a hypodermic, three to seven drops of suprarenal extract solution (1/1000) relieved many attacks as promptly as morphine, and more permanently. The suprarenal substance in two-grain doses combined with five to ten drops of ichthyol, in capsules, three or four times a day, improved conditions between the attacks and rendered the latter less frequent. In the study of each individual case, and in the hope of isolating, if possible, the particular toxic albumin that produced the paroxysm, lay our greatest hope for the future treatment of asthma.

Dr. William H. Thomson said he differed almost *in toto* with Dr. Hutchinson's remarks. In the first place, asthma illustrated better than other disease the mischief of interfering with regular nervous habits. In the act of respiration we had the most perfect example in the body of an habitual afferent impression followed by an habitual efferent excitation. This was presided over exclusively by the respiratory center in the medulla, and the result was that we had a perfect pendulum movement that continued throughout life as a settled habit. Now, suppose we stopped the backward swing of the pendulum by the act of coughing? This interfered with expiration for the time being. Suppose this act of interference constantly recurred throughout the day and night? What would be the result? We were setting an asthmatic habit, because in these cases we had no difficulty in inspiration, but a stoppage in expiration, and in at least 75 per cent. of cases, asthmatics gave a history of a prolonged period of coughing in childhood. When we once broke a normal habit we generated a remarkable susceptibility on the part of that center to impressions which did not affect it in health. This accounted for the extraordinarily whimsical character of the disease. We had already heard that one asthmatic could not endure a horse, while a cat produced an attack in a second one. This was not due to any mysterious poison emanating from these animals, but to the fact that the involved nerve centers of those individuals had become extraordinarily susceptible to excitation. The remedies for the treatment of asthma were of two kinds, totally different from one another. The remedies of one class acted simply upon the symptoms, and their entire effect was produced in one dose, providing a sufficiently large dose was given. Those of the second or curative class were limited, in the speaker's opinion, to two remedies, namely, arsenic and potassium iodide or some other preparation of iodine. In addition to this, we should treat the patient rather than the disease. Each case required individual attention, and any local source of irritation in the upper air passages or elsewhere should be eliminated.

Dr. Louis F. Bishop said he agreed with Dr. Hutchinson's views rather than those of Dr. Thomson. He looked upon the asthmatic type of disease, in a great measure, as a circulatory matter. These patients had a loss of tone in some part of their circulatory system, and he found by actual observation that persons who had asthmatic symptoms of one kind or another suffered from a relatively low blood pressure—not from an actual low blood pressure, but the pressure was low for that particular individual. The typical asthmatic attack was closely allied to hay fever, and was undoubtedly a vasomotor paralysis involving the vessels in the lungs as well as the vessels generally. It was dependent on a relatively low blood-vessel tension, local or general, and treatment should be directed towards the circulatory system.

Dr. Harlow Brooks said that one explanation that might be offered for the beneficial results that had been reported from the use of diphtheria antitoxin in a number of cases of asthma was that it increased the resistance of the body. While none of our methods of treating asthma could be regarded as brilliant from the physician's point of view, they were often very comforting from the standpoint of the patient, even though the improvement was only temporary. Of the newer remedies, the speaker said he had tried suprarenal extract with brilliant results in some cases, in one instance giving a dose of 30 minims. He also emphasized the study and control of each individual case, and the beneficial effect of climatic change.

Dr. Jefferson Scales said that in a certain number of his own cases the asthmatic attacks were attributed to a chronic bronchitis or protracted cough, or to some extraneous cause connected with the lung, such as pleuritic adhesions. He could recall cases that were attributed to badly smelling oil stoves or to the dust emanating from feathers. As to treatment, he had seen more benefit from arsenic and potassium iodide than from any other drugs.

Dr. Ransford E. Van Gieson referred to the fact that cases of asthma were frequently under observation from childhood up, and he was able to confirm the statement of Dr. Thomson in regard to its being often attributed to a prolonged cough in early life. For the relief of the paroxysms, he was inclined to ascribe greater efficacy to the nitrites than to stramonium.

Dr. A. Ernest Gallant said he disliked very much to give an anesthetic to a patient with the mucoid type of asthma, and in those cases he made it a rule to give a preliminary small dose of morphine and atropine placed and dissolved on the tongue. The preanesthetic treatment of the local condition of the nose in those cases was very important. The danger of teaching these patients the cocaine habits should be kept in mind.

Compensatory Albuminuria: A Contribution to the Study of Clinical Albuminurias.—By Dr. Heinrich Stern. (See Vol. 75, page 1094.)

Dr. Kingman B. Page raised the query whether a large albumin molecule could pass through the kidney epithelium without inflicting any damage. So far as we were able to determine, there could be this transudation through the healthy renal epithelium. He believed that the majority of kidney lesions were due to changes in metabolism, and as evidence of this he cited the well-known form of compensatory albuminuria in athletes, which had been referred to as presenting the most typical form of acute nephritis. In that type we had actual injury done to the structure of the kidney. There was another type in which there was a definite change in the end-products of metabolism, and where this extra eliminative work was thrown upon the kidneys. Doubtless there were many cases of temporary albuminuria which were purely compensatory, and so far as we could determine, we might have a transudation of serum albumin or globulin from the blood through a structurally unaltered kidney.

Dr. Woods Hutchinson said the fact that the kidneys excreted certain albumins, globulins, and sugars when introduced into the blood did not necessarily prove that they were not somewhat damaged thereby. That they could secrete these deleterious substances without permanent damage was due to the resisting power of the organs.

Dr. STERN, in closing, emphasized the fact that the various conditions comprised by him under the term compensatory albuminuria had nothing whatever to do with a disease of the kidneys. By employing the designation "compensatory albuminuria" he wished to imply that the activity of the normally functionating kidney compensated for the deficiency of a number of organs concerned in metabolism by removing either surplus albumin or such proteins as, although occurring in normal amounts, were not attached to the blood. They were therefore useless for the economy, and also, presumably, poisonous under certain circumstances. Of course, there would ensue a loss of albumin, but this deficit never amounted to more than a few grams during the twenty-four hours. There was absolutely no proof that the normal kidney was not permeable for the albumin molecule. We had sufficient evidence that it was, but normally the albumin was attached to the blood, and was thus prevented from being excreted by the kidneys. The door to escape, in other words, was always open, but the albumin was tied by invisible though very material chains to the blood. The moment these chains were weakened or no longer existed there was nothing which could prevent the escape of the albumin through the kidneys and into the urine. Compensatory albuminuria was therefore not a condition which was caused by a renal lesion, but one which was entirely due to anterenal disturbances. The kidneys permitting the passage of the albumin were not only not diseased, but, on the contrary, were very strong and active. Compensatory albuminurias, if they occurred at an insurable period of life, were the insurable albuminurias *par excellence*.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE HUMAN SPECIES. By LUDWIG HOPF. 8vo, 457 pages; cloth; illustrated. Longmans, Green & Co., New York.

FAITH AND WORKS OF CHRISTIAN SCIENCE. By the Author of "Confessio Medici." 12mo, 232 pages; cloth. The Macmillan Co., New York.

GENERAL SURGERY. By JOHN B. MURPHY, A.M., M.D., LL.D. 12mo, 617 pages; cloth; illustrated; $2.00 net. Year Book Publishers, Chicago, Ill.

GENERAL MEDICINE. By FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, A.M., M.D. 12mo, 403 pages; cloth; illustrated; $1.50 net. Year Book Publishers, Chicago, Ill.

SPECIAL PATHOLOGY. By BEATTIE & DICKSON. 8vo, 599 pages; cloth; illustrated; $5.00 net. P. Blakiston's Son & Co., Philadelphia, Pa.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of July 31, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	504	146
Diphtheria	196	20
Measles	310	20
Scarlet Fever	91	11
Smallpox	—	—
Varicella	25	—
Typhoid Fever	56	10
Whooping Cough	58	16
Cerebrospinal Meningitis	10	8
Malarial Fever	..	..
Totals	1,250	231

Leptothrix Meningitis.—W. A. Milligan reports the case of a child of four months who after a fall had been dazed. On admission to the hospital the child was rigid and had increased kneejerks. There was conjugate deviation of the eyes and lateral nystagmus, well marked cranio tabes, and a bulging anterior fontanelle. The temperature was 101° F. and the pulse 104. On lumbar puncture a purulent fluid was obtained which contained an excess of polymorphonuclear leucocytes and a leptothrix bacillus. The disease ran an acute course and caused death in five days. At post-mortem examination the pneumococcus was also found in the meningeal exudate. —*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 30, 1909:

		CASES.	DEATHS
SMALLPOX—UNITED STATES.			
Indiana, Muncie	July 3–10	3	.
Minnesota, Duluth	July 9–15	4	.
Missouri, St. Louis	July 10–17	1	..
Montana, Butte	July 8–15	4	.
Tennessee, Knoxville	July 10–17	2	.
Texas, San Antonio	July 10–17	1	.
Wisconsin, Appleton	July 10–17	4	.
SMALLPOX—INSULAR.			
Philippine Islands, Manila	May 28–June 5	1	1
Algeria, Bona	June 1–30	.	7
Argentina, Buenos Aires	Apr. 1–30	.	6
Brazil, Bahia	June 4–11	6	2
Sao Paulo	June 6–13	.	3
China, Hankow	June 5–26	.	Present
Shanghai	June 5–26	.	2
France, Marseille	June 1–30	.	5
India, Bombay	June 15–22	.	7
Calcutta	June 5–12	.	18
Rangoon	June 5–12	.	4
Java, Batavia	May 29–June 5	2	.
Italy, General	June 27–July 4	16	.
Naples	June 27–July 4	32	4
Russia, Odessa	June 19–July 3	5	..
St. Petersburg	June 12–19	27	8
Warsaw	May 22–29	.	2
Spain, Barcelona	June 28–July 5	.	5
Madrid	June 1–30	.	84
Valencia	June 19–26	6	.
Turkey, Bagdad	May 8–29	.	Present
Bassorah	June 19–26	.	Present
YELLOW FEVER.			
Brazil, Bahia	June 4–11	5	3
Para	June 19–26	4	4

THE MILITARY OBLIGATIONS OF THE MEDICAL PROFESSION.

BY LT.-COLONEL JEFFERSON R. KEAN, U. S. A.,

WASHINGTON, D. C.

IN a speech made to both houses of Congress on December 3, 1793, Washington said: "I cannot recommend to your notice measures for the fulfilment of our duties to the rest of the world without again pressing upon you the necessity of placing ourselves in a condition of complete defence, and of exacting from them the fulfilment of their duties toward us. The United States ought not to indulge a persuasion that, contrary to the order of human events, they will forever keep at a distance those painful appeals to arms with which the history of every other nation abounds. There is a rank due to these United States among nations which will be withheld, if not absolutely lost, by the reputation of weakness. If we desire to avoid insult, we must be able to repel it; if we desire to secure peace, one of the most powerful instruments of our rising prosperity, it must be known that we are at all times ready for war."

Any one who is content with the information given in our school histories with regard to the conduct of the various wars in which we have been engaged will probably be of the opinion that on the whole we have done pretty well. The careful military historians, however, see the other side of the shield, and two publications in the last five years have produced a profound impression upon military students as to our helplessness in the face of sudden attack and the grave extent to which we have ignored the advice of the Father of his Country.

Mr. Root, when Secretary of War, found in the files of the War Department, in manuscript, a work by General Emory Upton, entitled "The Military Policy of the United States," which he caused to be published in 1904. Two years later, in 1906, Mr. Frederic Louis Huidekoper published in the *North American Review* an article for which Mr. Taft, then Secretary of War, wrote an introduction which began with the sentence—"Every American who has the defence of the country seriously at heart ought to read Mr. Huidekoper's article, 'Is the United States Prepared for War?'" In this is given an interesting table showing in our ten wars, beginning with the Revolution and ending with the Philippine Insurrection, and including four Indian wars in which volunteers were called out, the forces engaged, the cost, and the pensions. He goes on to say: "Probably not one American in a hundred thousand has any conception of the outrageous extravagance in men and money that has characterized every war in which we have been involved. From a purely business standpoint, the above figures are indicative of puerile short-sightedness and criminal blundering such as would not be tolerated for a moment in any properly managed company or corporation in the United States." One example drawn from Upton will suffice to demonstrate how needlessly extravagant we have been, considering how disproportionately small have been the results achieved. Speaking of the War of 1812 he says: "The troops called out during this fruitless campaign (1814) numbered: Regulars, 38,186; militia, 197,653; total, 235,839. Of the militia 46,479 from the State of New York were employed on the Canadian frontier, while more than 100,000 from Pennsylvania, Maryland, and Virginia were called out to repel the incursion of the 3,500 British along the shores of the Chesapeake. Notwithstanding these enormous drafts, such were the faults of our organization and recruitments that the utmost strength we could put forth on the field of battle was represented at Lundy's Lane by less than 3,000 men. Nor was this evidence of national weakness our only cause of reproach. Boasting at the outset of the contest that Canada could be captured without soldiers, and that a few volunteers and militia could do the business, our statesmen, after nearly three years of war, had the humiliation of seeing their plan of conquest vanish in the smoke of a burning capitol." It may be judged from these extracts that neither of these works is flattering to our national pride, but each has been of great educational value.

Of the medical history of our wars still less is popularly known. It is even more melancholy reading. The tragic lack of organization of our medical department at the beginning of every war has been part and parcel of this general lack of system, and in fact it could hardly be expected to be otherwise. At the outbreak of the Civil War there was no organization for the removal of the wounded from battlefield. The ambulances were under the control of the Quartermaster's Department, and the surgeon controlled only his own two hands unless the doubtful assistance of the regimental band was vouchsafed to him. The professional activities of the surgeon in dressing wounds and amputating limbs on the battlefield did not greatly profit the wounded if they were left lying for days and nights where they fell, without food or drink or shelter. The following letter, which is on file in the War Department, shows the appalling suffering which was due to the lack of an ambulance corps:

SURGEON GENERAL'S OFFICE,
Sept. 7, 1862.

HONORABLE EDWIN M. STANTON,
Secretary of War.

SIR—I have the honor to ask your attention to the frightful state of disorder existing in the arrangement for removing the wounded from the field of battle. The scarcity of ambulances, the want of organization, the drunkenness and incompetency of

the drivers, the total absence of ambulance attendants are now working their legitimate results—results which I feel I have no right to keep from the knowledge of the department. The whole system should be under the charge of the Medical Department. An ambulance corps should be organized and set in instant operation. I have already laid before you a plan for such an organization, which I think covers the whole ground, but which I am sorry to find does not meet with the approval of the general-in-chief. I am not wedded to it. I only ask that some system may be adopted by which the removal of the sick from the field of battle may be speedily accomplished and the suffering to which they are now subjected be in future as far as possible avoided.

Up to this date six hundred wounded still remain on the battlefield in consequence of an insufficiency of ambulances and the want of a proper system for regulating their removal in the Army of Virginia. Many have died of starvation, many more will die in consequence of exhaustion, and all have endured torments which might have been avoided.

I ask, sir, that you will give me your aid in this matter, that you will interpose to prevent a recurrence of such consequences as have followed the recent battle, consequences which will inevitably ensue on the next important engagement if nothing is done to obviate them. I am, sir, very respectfully,

Your obedient servant,

William A. Hammond, Surgeon General.

Yet even this picture of 600 men lying for ten days on the battlefield of Second Bull Run could not overcome the prejudice of General Halleck against entrusting medical officers with the sacred function of command, even over the drivers and mules of the medical ambulances and the personnel of their own department, and he disapproved the recommendation of the Surgeon General. This essential service was, however, created for the Army of the Potomac about this time by General McClellan, apparently without reference to the War Department, upon the advice of his chief surgeon, Jonathan Letterman, one of the greatest men whose names adorn the annals of military surgery. This organization of Letterman's was finally in 1864 authorized by law and has since been adopted by all civilized nations. It was probably the greatest single step ever taken to reduce the suffering of the wounded in battle.

A distinguished member of the general staff remarked to me not long ago that it was inexplicable to him how a nation as altruistic in its impulses as ours could neglect to make proper provision for the care of its sick and wounded in war in the way that has happened in all our wars. I think, however, that the American people are not indifferent to the care of their sick and wounded, and the failure to make proper provision for them in past wars is due, as it has been in the case also of our English cousins, to a failure to understand what things are necessary to be done in order to secure efficiency. This is no surprising, as the question is technical, and the same lack of grasp of the question has been shared by the War Department, whose duty it is to inform Congress as to the needs of all parts of the military establishment.

A recent remarkable article by a distinguished English general, Field Marshal Sir Evelyn Wood, called "Tactics and Health of the Army," shows that from the same source proceeded the opposition to sanitary progress in the British military service. This article and the remark I have first quoted show, I trust, that hereafter we may hope for assistance where we have hitherto encountered obstruction. My time is too limited to quote interesting illustrations of the appalling losses in lives and efficiency produced by sanitary neglects and the inefficiency of medical administration in our wars. I will only to-night attempt to state baldly what is necessary in the way of preparation for the future.

The duties with which the Medical Department of the Army is charged in time of war are as follows: (1) Preservation of the health of the army. (2) Professional treatment and care of the sick and wounded. (3) The collection of the wounded after battles and of the sick in the field, and their rapid and comfortable removal from the zone of active operations. (4) Such organization of the medical service as will secure the prompt return to the ranks of the sick and wounded as soon as they have recovered. (5) Furnishing the necessary and appropriate medical equipment and supplies for the medical service; and (6) The preparation of the medical records and reports necessary for good administration, and to provide that the interest of the soldier as well as that of the government be safeguarded. Under this head comes most of the red tape which is the bane of the volunteer surgeon. Of these six obligations you will observe that only one, the second, can be performed by the well qualified practitioner without previous military training and experience.

These being the duties of the medical service, the next question is how they may best be carried out. This question was very fully studied by a commission appointed by President McKinley to investigate the conduct of the Spanish War. It was also investigated by a similar commission for the British service as regards the Boer War. The conclusions of the two commissions are so much alike as to be almost interchangeable, the cardinal error being, in both countries, the failure to provide for the regular army in time of peace the full number of trained medical officers which a logical organization demands. I wish to say in passing that, with this one exception of an adequate personnel (and this has been much improved by recent action of Congress), the Surgeon General was able to state in his last report that all of the seven recommendations of the Dodge Commission have been or were in process of being carried out.

Until recently line officers were quite inclined to think of the duties of the medical officer as limited almost entirely to professional treatment and the furnishing of medical supplies, and I think such is still largely the opinion of the laity. Yet it is not difficult to see that the prevention of disease is of primary importance. Also from the cold, unsentimental, practical point of view of the efficiency of the army as a fighting machine, the fate of the sick or wounded man who cannot be returned to the ranks is of no importance except for its effect on the morale of his comrade. It is likewise extremely important that the army shall preserve its mobility and be disencumbered of the sick and wounded, and that those who promptly recover are returned to the ranks. After modern battles the number of quick recoveries from bullet wounds is very large—amounting, as is estimated, to one-third of the wounded within one month. This failure to return convalescents to the ranks was a constant source of complaint during the Civil War, and was one of the drawbacks to the intervention of the Sanitary Com-

mission and other civil agencies in the work of the medical department.

The prevention of the infectious diseases was, until very recent years, when the methods of transmission have become accurately known, not on a scientific basis, and the partial measure of success attained was by following empiric rules born of experience. As late as the Spanish-American War we did not know the method of transmission of malaria and yellow fever, the two diseases which, in six weeks, reduced the disciplined and gallant little army of Gen. Shafter to absolute impotence. We thought we knew something of the transmission of typhoid fever, but our experience in civil life led us to believe that it would be in the army principally a water-borne disease, and it required much bitter experience and the exhaustive investigations of Reed, Vaughan and Shakespeare to teach us that the epidemic typhoid of the volunteer camps was a contact infection, with fly transmission as a secondary factor, water infection being practically excluded. Now, however, preventive medicine has reached a high degree of efficiency in the army, and is a matter in which the more progressive officers of the line are beginning to take a keen interest. Its application requires, however, a large increase in the number of medical officers authorized for the army as compared with the proportion which formerly sufficed, and some of this increase must be highly trained specialists. The powers that be have heretofore shown a decided unwillingness when the army has been increased to supply the simple rule of arithmetical proportion to the medical corps by giving the medical staff the same increase which has been given the army as a whole. As a result of this attitude the number of officers in the medical corps is now less in proportion to the strength of the army than it was at the beginning of the Spanish War, or of the Civil War, or of the Mexican War, and even when the medical corps is filled to its authorized strength in 1911 the proportion of medical officers will still be less than at the beginning of any of our wars. When, therefore, a larger proportional increase is asked in order that the new responsibilities may be successfully met, it is to be feared that much opposition will be encountered.

It has been demonstrated by the Surgeon General that to man the field organizations of the medical service and the service of the line of communications and base, the strength of the medical corps should be one per cent. of the strength of the army. It is at present about one-third of one per cent. There is no reason why the medical organizations of the regular army should go into a war short handed any more than any other part of the army. They will be promptly depleted in any event to supply trained men for various administrative positions where their services may be needed with the volunteer troops. The proportion stated seems large, but the necessity becomes apparent when, in addition to the number of officers employed in sanitary work, we consider the method in use for the evacuation of wounded and sick from the army in the field. The field hospitals, of which there are four with each division, being marching organizations, are intended to receive and shelter serious cases only until they can be passed back successively to the evacuation hospitals, and thence to the base hospitals. Therefore, these units stand one behind another and pass the sick and wounded along like a row of men pass buckets of water to a fire in a country town. The method is expeditious and effective, but it requires a large personnel, and there must be no gaps in the line or the system will break down.

Our cardinal need is thus a full quota of trained medical officers for the army in time of peace. This is what we must have, and my message to you tonight is to ask your persistent and active aid in demanding this of the War Department and of Congress. We need, however, something more—we want men. The granting of a logical organization will not help us unless we can fill it with capable, efficient young men. There are at present 104 vacancies in the medical corps of the army. The pay, allowances and status of medical officers, and their prospect of promotion, have all been recently greatly improved by the action of Congress, and we can now offer what we could not a year ago—an attractive career to the young medical graduate. A young medical officer upon admission to the corps is given the rank of first lieutenant and his pay is $2,000 a year. He is furnished, in addition, with a commodious house, furniture, horses, fuel, lights, forage, professional books and instruments. He receives many things in the way of gratuitous personal services. He can purchase supplies from the Government at cost. When he travels under orders his expenses are paid and the Government packs and transports his property, and when necessary stores it for him without charge. At the end of three years he is promoted to captain and his pay is raised to $2,400; at the end of two years more he receives a further increase to $2,640. I think it is a fair estimate to say that upon entering the service he gets in the way of pay and allowances the equivalent of $3,400, and at the end of five years' service the equivalent of $4,000 a year. I am inclined to doubt whether the pathway of the beginner in civil practice is so strewn with roses and with dollars and his professional services are in such demand that these positions can be considered unworthy of notice. It must be that young graduates are not well informed as to the excellent prospects afforded by the medical services of the army and navy. I believe if each member of this society would make it his duty to speak to one or two young men who are about completing their hospital course and are ready to begin practice, that our Army Medical School would be next winter full to its limit with candidates for the corps.

The policy of the department is to give medical officers constantly greater opportunities for special study and professional advancement, and the service is not now a monotonous round of sick calls and hospital work. It is varied by many opportunities for special work of interest and importance. Col. Gorgas, with several assistants from the army, has sanitary charge of the great national enterprise at Panama, where success spells fame, and, it is to be hoped, high reward. Ashford, with King, of the Public Health Service, not long since conducted a two-years' campaign which rescued the coffee raisers of Porto Rico from universal hookworm infection. I have myself recently returned from a tour of two and one-half years as sanitary adviser to the Cuban Government, where I had the pleasure of preparing the new law which will, I trust, give Cuba a model sanitary organization.

A medical officer has just been detailed for work at the Rockefeller Institute; another is a lecturer on tropical medicine at the Post Graduate School in this city. A number of our men have taken courses at the London School of Tropical Medicine, and others are now members of a board for the study of

tropical diseases in Manila. Almost every month medical officers are sent to represent this country at international congresses abroad and important societies at home. In the Russo-Japanese War medical officers were assigned as observers on both sides, and a medical officer is at present hunting lions and butterflies with Mr. Roosevelt in Africa.

I have not yet stated the full list of our necessities. We need a careful system of training for the medical personnel of the organized militia, which is a part of our first line of defence. This should be uniform throughout all the States and should be promoted and assisted in every way by the War Department through its militia division. We need also to have a large number of capable, well educated young men on the rolls of our Medical Reserve Corps, who will be available in time of war and receive some instruction in time of peace by being called out for a week or two of duty at the maneuver camps. It is the intention of the department to make the examinations for the commission in the reserve corps as rigid as is the examination for permission to practise in any State. It would greatly increase the value of these commissions if the State authorities in each State would confer on the bearers of them the right to practise in any State. This would also greatly advance the cause of interstate reciprocity and the creation of a standard of medical education in this country.

Our sister service, the navy, is always near a war footing, and necessarily cannot be rapidly enlarged, and so it does not suffer to the same extent from the wants, the neglects, the disgraces of a sudden and vast expansion for which provision has not been made in advance.

But for the army, the only limit to its expansion is the number of men capable of bearing arms. In the same way the only limit to the increase of the medical department in war is the number of physicians in the United States. It is, therefore, proper that each member of this society should regard himself as a part of the great medical reserve of the nation in arms. It is among all nations an obligation of the citizen to give service in arms to his country in time of need, and I take it to be the duty of a good citizen to take some thought and give some effort in the way of preparation against the evil day. It is at the beginning of wars that the sick and wounded have always suffered most from confusion and lack of organized method, and, therefore, any help which each of you will give to promote the preparedness of the medical service is a valuable and appropriate contribution in discharge of your patriotic duty.

SOME FEATURES OF THE MEDICAL DEPARTMENT OF THE NAVY IN PEACE AND IN WAR.

By CHARLES F. STOKES, M.D.,

SURGEON UNITED STATES NAVY.

As the scope of the duties of medical officers of the navy is so little appreciated outside the service, and particularly by physicians in civil life, it will perhaps be well to devote the few minutes allotted to a consideration of our field work in general rather than to dwell upon some interesting feature of our daily routine.

I know of no body of medical men who are taken less seriously by the public in general than are medical officers of the navy. The public knows that the requirements for entrance are of a high standard, and it believes that we, as a rule, are pretty well equipped at the outset; and it is equally true that it pictures us afterward comfortably housed in luxurious battleships, with little or nothing to do but to look after the trifling ailments of rugged, husky, young fighting men. It believes, too, that the navy offers a very limited field for develpoment along purely professional lines. Possibly this was true prior to the present decade, but conditions have changed radically since the Spanish-American War. The best minds in every corps of the navy are seeking to add to efficiency; the spirit of rivalry among the various corps keeps up enthusiasm and tends to do away with laggards. You have noted with pride, no doubt, the marvelous advance in numbers and types of ships and the wonderful strides in gunnery in recent years; it gives me pleasure to assure you that the medical corps has kept pace with the others, although, as is usual, little of the glory or glamour has come our way. The unceasing efforts of Surgeon-General Rixey have made this progress possible.

In taking you over our field of work it will be well to point out to you the material we have to work with, where it is recruited and how, what is done with it to shape it into the up-to-date fighting man, and how preventive medicine, including prophylaxis, hygiene, and sanitation, has been implanted upon the service. The drills in first aid to meet battle conditions on board ship and on shore and sanitary instruction will be considered. We shall thus far have dealt with the selection of suitable material for the personnel, its protection from mishap and disease, and the instruction given to care for the accidents and emergencies of peace times, which naturally is doubly important as a preparation for war. I shall then briefly state how and where the sicknesses and injuries these fighting men are incident to are cared for. You will be surprised, without doubt, at the extent of our equipment and the amount of work we are doing, and particularly the special lines of work that are being pursued. The question of handling the sick and wounded in time of war will also be discussed. Naturally, such a broad field can only be dealt with in a cursory way in the short time available; nevertheless, I shall endeavor to emphasize the special features of our work that merit particular attention and in the advancement of which we look to the great medical body in civil life for encouragement and support.

The fifty or sixty thousand sailors and marines of the fighting establishment represent but a small proportion of the number of individuals we care for. There is that great body of civil employes at our various navy yards and naval stations, officers' families, retired officers and their families, the inhabitants of our island possessions, and thousands at Panama and elsewhere.

You have never fully realized, in all probability, that each one of the fifty or sixty thousand officers and men is subjected to a painstaking, careful physical examination by a medical officer or a board of medical officers of the navy. In the case of the enlisted men, the examination comprises a lot of detail work, and is in no sense a perfunctory procedure. The sight is tested, the hearing tried, the color sense looked into, the teeth inspected, likewise the mouth, fauces and nares, and all abnormalities are noted, whether the applicant is rejected or not. He is stripped and looked over for ankyloses and

deformities—for hernia, for hemorrhoids, for fistula, for venereal diseases, and for lung and cardiac lesions. Each candidate is weighed and measured, and, for purposes of identification, all scars and physical characteristics are noted, and thumb and finger prints are recorded as well. This enlistment record follows the man throughout his career in the service, is added to from time to time, and is finally filed at the Navy Department for reference in connection with possible future pension applications.

Upon the care with which these important examinations are carried on depends the physical make-up of the fighting men of the navy. Loose recruiting methods have led to no end of trouble in the past, particularly when it has been necessary to employ the services of physicians in civil life who are generally not familiar with the peculiar features of the service that demand a high physical standard and no varying from it. The medical officer on recruiting duty, and when serving on boards for the physical examinations of officers and others, must assume the mental attitude of the insurance examiner, differing only in that he should be more painstaking in his examinations and more conservative in judgment, for he is dealing with the safety of human lives, possibly the destiny of the nation, not with dollars alone, as in the case of the insurance man. He should search for defects that may make the applicant a bad investment for the government—poor material to be whipped into shape, and which, if overlooked, might possibly lead to a life pension.

When we are detailed to serve on boards for the physical examination of midshipmen we have a complicated problem in hand. High physical standards are required. It is not at all difficult to determine who comes up to these standards and who does not. The findings of these boards should be final, but they are not so in any sense. When a midshipman learns that he has been found physically disqualified, and has been recommended by the board to be dropped, he at once sets his protective machinery at work. His Congressman is usually communicated with early, and the next move is to consult either the optimistic oculist, the optimistic heart man, or some other optimist in civil life. Armed with the every-ready optimistic certificate from the civil optimist, the Congressman calls upon the Secretary of the Navy, who is placed in a difficult situation, and naturally looks to the Surgeon-General to help him out. If the department does not dispose of the case at once, it is probable that the board will be asked to reconsider its findings. Having already carefuly considered the case on its physical merits, with the best interest of the service before it, and at the same time safeguarding the interests of the individual, the board rarely changes its conclusions, and in the end the Navy Department finally disposes of the case as it sees fit.

When you gentlemen are asked for a certificate as to the physical qualifications of a rejected midshipman, ask yourselves whether or not he is of the physical make-up to stand the enormous mental and physical responsibility of taking a great battleship with its thousand or more souls into action, or perhaps to lead a fleet into battle, when possibly the destinies of this great nation hinge upon his behavior. Only those who are physically and mentally sound can be relied upon under such conditions as these, and the country should have the services of this type and not those in the doubtful class, physically and mentally. When you, through sympathy or other perfectly natural motives, help to patch up and bolster through those who are physically defective, you assume a very grave responsibility. It is generally believed that we are not familiar with the refinements of diagnosis in heart cases, that we cannot appreciate or differentiate between hemic, accidental, so-called functional and cardiac-respiratory murmurs, and the valvular and other organic lesions. It is assumed that we know little about eye cases. To examine between eight and nine hundred midshipmen is an education along these lines in itself, particularly when one has become familiar with various types in the service. Bear in mind the marvelous changes that have taken place in the navy in very recent times. It was customary for ships to cruise singly; fires were hauled after getting to sea and ships proceeded under sail; there were few cables and little to disturb peace of mind. To-day ships cruise in fleets, cables are ever present, the wireless apparatus is going day and night, signals are incessant, evolutions are carried on constantly; the danger of collision is real and must be averted. Competition in gunnery is keen; drills are frequent. Then, too, we have duty on torpedo boats and submarines and shall soon be navigating airships. These changed conditions have made a serious impression upon naval officers already. Reflect upon the foregoing, put yourselves in our places, and you will, I believe, examine your midshipman from the only logical viewpoint.

So much for the material we have to deal with professionally. How do we safeguard this material from disease and injury? First, let us consider nutrition. All water in use on board ship for drinking purposes and in the preparation of food is distilled. The navy ration has been worked out upon scientific lines, and the necessary number of calories are provided for. The supply ships of the fleet are stocked with fresh meat and vegetables in abundance, and each warship is equipped with an ice plant. A much-needed school of cookery has been established for the instruction of navy cooks; this, in time, will lead to the proper preparation of the ration and the prevention of undue waste. Painstaking care has been devoted to the hygienic features of lighting, heating, and ventilation of living spaces on board ship. Dryness has supplanted moisture between decks, and the common drinking cup has disappeared. Each hospital ship carries a dentist, and it is amazing to see the numbers of men who, of their own accord, apply for dental treatment.

Enough has been said to show to what extent preventive measures prevail in naval practice. Most gratifying results have followed the systematic prophylactic treatment of venereal disease. In the old days I have seen a ship leave the Asiatic station with 90 per cent. of her crew syphilitic; to-day the percentage is not more than two or three, if that much. While these satisfactory conditions exist on board ship, we are unable to control our men on shore; and sooner or later, when we remain long in a port, they acquire a fair share of the prevailing diseases of that particular locality if given much shore leave. As our men are young and recruited from rural districts, where the common diseases of childhood do not prevail, these diseases find virgin soil in the navy, which accounts for the frequent outbreaks of measles, diphtheria, scarlet fever, chickenpox, and other diseases of this sort. When the Atlantic fleet arrived in Honolulu, 10 days from San Francisco, there were 59 cases of contagious diseases distributed among the ships.

Let us see what provision is made for the care of the sick and injured of the personnel afloat and ashore. This matter naturally is in the hands of the medical corps, which, with all vacancies filled, is one of the largest specialized bodies of medical men in the world. There will, when the corps is full, be 345 regular medical officers and 25 acting assistant surgeons, making a total of 370. There are about 1,100 hospital corps men and the recently organized female nurse corps serving under the medical department and already on duty. There are 18 hospitals now in commission, and they may be compared in size and capacity with the General Hospitals of the Army. Two new 350-bed hospitals are to be built in the near future, one on the Great Lakes, the other at Pearl Harbor, near Honolulu, in the Hawaiian Islands. In addition, we have two hospital ships, the Solace and the Relief. The medical and surgical equipment of these establishments is thoroughly up to date. In addition to the hospital ships, each warship has its own hospital or sick bay. Each of the battleships and armored cruisers is provided with a sick bay with a varying number of beds, bath room, operating room, store room, examining room, dispensary, and an isolation ward. Such a plant may be likened to a post hospital in the army. You will no doubt be surprised to learn that many of these hospitals are taxed to the limit of their capacity.

You will naturally be curious to know what classes of cases we treat in our hospitals. Much the same as you see in the great civil hospitals, barring women and children, while in the tropics—in Porto Rico, Samoa, Guam, the Philippines, and at Panama—tropical diseases prevail. As might be expected, various types of traumatism are of frequent occurrence on board ship, and these mishaps are apt to be met with at most inaccessible points, making transportation methods complicated and difficult. This will be appreciated when you stop to consider the many water-tight compartments, the turrets, magazines, coal bunkers, and the like which go to make up the modern fighting ship. The transportation apparatus which seems to meet these unusual conditons best is the splint stretcher devised by the writer several years ago, and now in use both in the army and navy.

You must not lose sight of the fact that naval medical officers serve in the field and on shore with the Marine Corps—some 10,000 officers and men—and, too, that there has been no recent war in which the navy has not participated in operations on shore. Many naval medical officers have served with foreign armies as well. It is evident that we should be prepared to cope with the exigencies of service with troops on shore.

A number of naval medical officers are engaged in special work. Some are devoting themselves to diseases of the eye, ear, nose, and throat; others are giving their attention to surgery; still others to tropical medicine, pathology and bacteriology, and to naval hygiene. One has command of the Hospital Corps Training School; another has charge of the Naval Medical Supply Depot, and purchases practically all the medical and surgical equipment for the navy. Others are on duty at the Naval Hospital at Las Animas, Colo., which is assigned to the treatment of tuberculosis, and where Surgeon Barton L. Wright, of the navy, has put his treatment of that disease, by means of succinimide of mercury, on a scientific basis and has attained brilliant results well worthy of careful study. At the Naval Medical School nearly all the instructors are naval medical officers who have specialized in the branches they teach. The Bureau of Medicine and Surgery publishes *The Bulletin*, a journal restricted to the observations of medical officers on board ship and at shore stations.

Let us now take up the question of the medical department of the navy in war. Theoretically, all departments of the navy should be on a war footing at all times. It is too late when war is imminent for the navy to attempt to expand. If actual hostilities were to be declared to-day, the breakdown in the medical department of the navy would be as appalling as any that has occurred in recent times. First-aid instruction as now given is utterly ineffective. On a battleship carrying nearly a thousand men, two medical officers have this instruction to give, and this for short periods at comparatively long intervals. The matter is not taken seriously. The line officers should instruct the men, and this instruction should be a part of every drill with guns, great or small. From 5 to 10 minutes of each drill period devoted to the work would soon solve this problem. The medical officers should confine their efforts in first aid to preparing the line.

The fighting men know what they can do in the matter of hits, and they should be made to realize that the enemy is going to be just about as effective as they, and that the preparation for probable injuries should be seriously considered and should be associated with the weapons of offense. Let us suppose that the Atlantic fleet on its recent cruise had engaged an equally powerful enemy, what would have been the result? From the lessons of the Russo-Japanese War we have learned that we must provide for 30 per cent. of casualties. What would we have done with 5,000 wounded if the action had taken place at a point far removed from a base? The hospital ship, Relief, with its 215 beds, would have been about as much use as a dressing station to an army. As a wireless outfit was denied this ship, in order to keep within signal distance, it would have been obliged to remain within the danger zone, and would therefore have stood a good chance of being destroyed. When one gives the best there is in one for one's country and one's flag, common humanity demands, aside from all questions of military efficiency, that proper provision be made to minimize one's suffering and make recovery possible, should one be wounded.

To meet this situation, there should be one spacious, stable hospital ship with a capacity of at least 500 beds with each fleet, and at least one fast ambulance ship with each fleet as well to act as tender and medical transport, to be employed in removing the wounded to shore hospitals. A naval medical reserve corps should be established, so that those whose services wil be required in war times shall be familiar with their duties and the peculiarities of the naval service. Properly appointed hospital ships should be specially built for the purpose. The ordinary merchant steamer is just about as useful as a hospital ship as it is as a fighting ship. At least two hospital ships should always be in commission for drill purposes, and each should always be commanded by a medical officer with a competent navigating officer under him. This arrangement worked with perfect satisfaction on board the Relief. To equip, organize, and run properly a 500-bed hospital afloat is an undertaking requiring executive ability, force, skill, and tact; the unusual problems incident to such a command should all be worked out

in actual practice in time of peace. The hospital ship should not be a novelty in the fleet. As a drill in the varied features of neutrality in naval warfare, its existence is justified. Had the hospital ship, Relief, continued on with the Atlantic fleet from Manila to Hampton Roads, it would have been in the vicinity of Messina at the time of the recent appalling disaster at that place; and with its many beds, superb equipment in the medical department, large quantities of medical stores and field outfit, it could have rendered a service which would have reflected great credit on this nation and have added another triumph of peace to the record of the battleship cruise.

Had the earnest pleadings of the Surgeon-General been successful, the Atlantic and Pacific fleets would each have had a spacious, well-equipped hospital ship at hand when earthquakes devastated Martinique and leveled Kingston in the Atlantic, and practically destroyed San Francisco on the Pacific side. At this moment, without doubt, if such a ship were in commission, it would be steaming toward Constantinople.

If this cursory consideration of some of the problems that daily confront the medical corps of the navy has brought anything new to your notice, I shall be well repaid for preparing it. The medical corps of the army and that of the navy work hand in hand, and I hope in the near future to see us in closer touch with the national guard and our colleagues in civil life.

THE NATIONAL GUARD SURGEON.

By WILLIAM G. LE BOUTILLIER, M.D.,

NEW YORK.

LIEUTENANT-COLONEL, DIVISION SURGEON, NATIONAL GUARD, N. Y.

In the National Guard of New York State there are about 120 officers commissioned as surgeons and assistant surgeons of varying rank. About one-half are stationed in Greater New York, 20 in Albany, Buffalo, and Rochester, 3 each in Binghamton, Troy, and Utica, and the remainder, 32, at 20 widely separated cities or towns where there are armories for separate companies.

Commissions are given by the Governor of the State to candidates who have passed the prescribed physical and professional examinations before a board of medical officers. The professional examination is oral. The board no longer examines in anatomy, physics, chemistry, and physiology, on which subjects few physicians are prepared for a real examination at the period after graduation when most candidates come before it. The principal subjects on entrance are general medicine and surgery, the treatment of diseases and injuries to which troops are exposed, and camp and personal hygiene. The examination for promotion is almost entirely on military subjects and administration.

The official title of surgeon or assistant surgeon is a relic of the days when a medical man in the militia was first and foremost and frequently only a doctor, with duties almost entirely confined to treating men after they had become sick or were wounded. These titles are now omitted when a physician is commissioned in the Army Medical Corps, and it is expected that this State will soon make the same change, which reflects the progress of preventive medicine and the corresponding change in the duties of a medical officer.

It is not many years since the chief qualifications of a physician for a commission as a surgeon in the organized militia apparently were a love of wearing a uniform with a liberal amount of gold lace, a facility in telling stories of easy virtue and any age, and the time and ability to stay as late at any social function as the supplies of tobacco and drinkables held out. Equally important was it that he could be readily hypnotized so as to perceive, at the suggestion of a recruiting officer, that an undersized or physically defective recruit was a husky citizen of unusual vigor and muscular development.

But these happy, careless times have passed, and the physicians who hold commissions in the Medical Department of the National Guard of this State at present are expected and required to have very different abilities and to work very hard. In a general way their duties resemble those of medical officers in the army, but there are some important differences. In the State service medical officers comparatively seldom have any military patients to treat; they do not ordinarily purchase or issue the medical stores needed; their hours of duty are not the daylight ones, for except for a week every year or two when in camps or at maneuvers, they give their services in the evening after attending to their daily occupations; and they spend a larger share of the time they give to the State in examining recruits, and in training the enlisted men of the hospital corps. With a regiment there are usually four medical officers, and if the work is to be satisfactorily done, each, as a rule, must spend at least two evenings a week at the armory for eight months of the year. In addition to this a large amount of time has to be given to reading and study.

When called into active service, or at camps and maneuvers, there is no essential difference in the duties of medical officers of the army or of the National Guard, except that in the State service more time has to be given to teaching both the hospital corps and the officers and men of the line. The National Guard is an educational organization and every officer has to be both a teacher and a student.

When not on active service the principal duties prescribed for medical officers in the National Guard are to enlist and train the men of the hospital corps, to examine recruits, to keep on hand in readiness for active service the medical supplies authorized for such service and issued by the Adjutant General of the State, to teach hygiene and sanitation and the principles of "first aid" to the line officers and the enlisted men of the hospital corps, and to learn to perform their own duties.

When at the camps or maneuvers, or on active duty in case of riot or strike, they advise commanding officers as to sanitation, make sanitary inspections and reports, care for and keep records of the sick, care for hospital corps men and train them in practical sanitation and field work.

From the point of view of the average line officer a medical officer is a necessity or a necessary evil in order that recruits may be examined physically. At some of our company posts they do without one and have their recruits examined by physicians not in the National Guard. The line officer rarely takes any interest in the hospital corps or in the training of the medical officer to perform his military duties, nor does he at present often realize that in the field an efficient medical department is as important as the supply of food, shelter, and ammunition.

The examination of recruits is indeed a very important duty and one that requires some training to perform quickly and skilfully, though it is of far

less importance than the line officer apparently regards it. The rejection of those recruits who do not fully satisfy the standard requirements is essential, so that the troops may be physically sound and able to respond to the calls on their strength and endurance that will certainly be made upon them in any active service. The examination should be as cold-blooded in its requirement of fitness as the judgment of a veterinary surgeon as to the soundness of a horse. It is not exactly like an examination for life insurance, and it is very unlike the physical examination of a patient in whose case treatment is to follow the diagnosis. To acquire a correct judgment of physical endurance and fitness takes some experience both in the actual examination of recruits and in the strain upon the soldiers incident to field service. The State wants only the best recruits and the best can be had. It is the duty of the medical officer to reject the others. We have so little field service and marching that many medical officers do not appreciate how much strength and endurance a soldier must have to march with his heavy load of field equipment, and they accept at times and too often unfit men on whose training the State wastes large sums of money, as a few days of active service exhausts them and they go on the sick list with claims for pay and can ask for pensions.

The enlistment and training of men for the hospital corps takes, or should take, rather, more than half the time of the National Guard surgeon. There are authorized to serve with each regiment thirty hospital corps men. Their duties are to care for the sick in the field, and to give "first aid" in case of accidents, to act as bearers, to pitch and equip tents, cook, drive and load ambulances, and care for the horses or mules used by the medical department. The number of them reported enlisted in February was 438, a gain of 15 in the preceding six months, but 200 less than the authorized strength. Of those enlisted August 31, 1908, there were 21 physicians, 9 medical students, 36 pharmacists or druggists, 5 trained nurses, 2 nurses, 5 hospital orderlies, 3 laboratory assistants, 3 veterinary surgeons, 1 chiropodist, 1 radiographer, 10 drivers, 2 horsemen or hostlers, or 108 men, one-quarter of the total strength whose daily occupation was in direct relation with the care, treatment, or transportation of the sick. But it should be noted that only 12, not 3 per cent., were nurses of any sort. The majority 107, of the other men of the hospital corps were clerks and salesmen, and 73 were mechanics or had some trade. Hardly any are laborers, and the average of intelligence is fairly high and sufficient for their duties.

The kind of training and degree of training that can be given to the hospital corps man is of interest. The National Guard maintains no permanent hospitals, and has no way of finding any clinical material to use for training in the actual care of the sick except when troops are in camp or on active service. At such times the number of patients is very small so that no adequate training as nurses or in minor surgery can possibly be given. In the State military service it would be a medical crime to keep the sick with the troops in tents, with rough field cooking, and incompetent nurses, as there are large numbers of hospitals accessible from any place where troops may be located. Accordingly the practice for some years has been to transfer all the seriously sick as soon as possible from the camp to some well-equipped civilian hospital where there are trained nurses, and place their medical or surgical treatment in the hands of physicians who are not necessarily in the military service. This of course entirely prevents training the hospital corps men as nurses, but it is more economical for the State, more humane to the sick for whose care and comfort better provision is made. It also avoids the danger of spreading communicable disease to the troops, makes the troops more mobile as they are not encumbered by sick, and leaves more time for sanitary inspection by medical officers.

What can be done with the hospital corps men is to train them to be soldierly and disciplined, to act as bearers and give "first aid," to erect and equip the hospital tents, to cook, and to transport the sick and wounded.

The field hospital mustered in three years ago is an organization whose real function is to transport the sick, not to treat them except when absolutely necessary, as after a fight. The National Guard being organized as a division, should have four field hospitals instead of only the one that as yet exists, and the number of enlisted men in each should be 118, while only 80 are authorized now on account of lack of armory space and money to provide uniforms and equipment. As the field hospital has little recruiting to do compared with other detachments of the medical department, it has been possible for its commanding officer, Major William S. Terriberry, to arrange a satisfactory course of instruction for its officers and men in their military duties. Nowhere else in the State are the medical officers and hospital corps men so well trained for their actual duties in the field. In the field a large number of them must ride, but at present they have little or no opportunity to learn to do so or to care for horses except those who are in the field hospital and about twelve officers and twenty hospital corps men attached to cavalry, field artillery, and signal corps organizations.

Actually the most important duty of the National Guard surgeon is to study military hygiene, the military law, regulations and orders, to prepare himself for service in the field and at the front. His duties bring him into constant and close relations with other departments, and he must know almost as much about subsistence and transportation as a commissary or quartermaster. He must know all about the management and control of a company as he has to care for his hospital corps men and the sick in hospital in the same way that the captain of a company of infantry or cavalry cares for his men. There is indeed nothing that he can know about military matters that is not likely to be at some time of service both to himself and to the troops with which he is on duty, and to increase his value and efficiency as a purely medical officer.

The National Guard surgeon must learn field sanitation not only by reading books but by acutal field experience. His responsibility is not for what is actually done in the field by the troops but for giving correct advice to his commanding officer. A highly important duty is to teach sanitation to the line officer, and to so conduct himself that he gains the confidence of his commanding officer so that his recommendations will be considered judicious and put in force. To care for troops properly it is necessary that every line officer should be interested and trained in military hygiene. If only the physically fit are enlisted, enlightened care of troops will maintain them in health, unless military necessity requires their expenditure by disease or

overwork just as any munition of war is expended to defeat the enemy. When the medical officer has taught the line officer that most disease is preventable, and how, the day will have dawned when troops will have to fear death from the enemy's weapons as much as from the ignorance or carelessness of their own commanding officers. To bring about such a degree of knowledge is a large and constant task for the physician in the military service. To those who are working toward its accomplishment the medical profession and the public owe a great deal, for the service is a very necessary one and the compensation quite inadequate.

THE HYGIENE OF THE REGIMENT.

By HARLOW BROOKS, M.D.,

NEW YORK.

CAPTAIN AND ASSISTANT SURGEON, SEVENTH REGIMENT, N. G. N. Y.

This very brief paper has been prepared in order that an idea might be given of those features of national guard life which render service in this organization attractive to medical men.

A doctor who joins the national guard does so, in most instances, I think, from a feeling of patriotism and in the expectation that his experiences in this service may prepare him for the duties of a medical officer of volunteers, should the country at some time need his services. It is all too generally thought among medical men that all that is necessary for a man to be an efficient medical officer is for him to be a good doctor. Our preceptors of the regular services can tell you that this is, on the contrary, but the primary or preparatory essential. Some of the most important duties of the military medical man are but little appreciated by those of us exclusively in civil practice.

One illustration of the difference in standpoint will perhaps suffice. In civil life we are chiefly occupied with the care and treatment of the sick; in military medical life one is chiefly concerned with the care and management of the well, that they may not become sick, and in case of sickness the chief duty to so dispose of the patient that without detriment to him he may not by his presence or helplessness hamper the activity of the military body. His treatment, except that which may be classed as emergency, may be well left to civil physicians. It is a somewhat brutal but none the less true saying that from a military standpoint a dead soldier is twice as valuable to a nation as one sick soldier; this because of the attendance and care which must necessarily be provided for the military sick and which must therefore be deducted from the fighting strength of any command.

Hence it is that the medical officer of a regiment is chiefly concerned with hygienic problems, and in this respect he should be far more efficient than a civil physician, both because of his special technical training and because of the authority vested in him by his rank, and therefore his ability to order and to put into force needful, though perhaps onerous, rules which would never be tolerated in civil communities. It is chiefly the experience and interest in this active, aggressive and militant hygiene which renders service in the medical department of the national guard attractive to the physician. He who enters the service with any other ideas or ambitions in mind is doomed to probable disappointment and his organization to more or less military inefficiency.

It is primarily assumed that the personal of the regiment is composed of healthy and altogether sound men. That this be so is the united duty of the line and the medical recruiting officers. It is then the primary duty of the regimental surgeon to see that each man remains in such condition that at all times he may be found in a physical condition fit for active service.

Among the most important duties of regimental medical officers serving with foot soldiers is the supervision of the care of the feet. All the care and solicitude which the mounted man bestows on his horse, for the infantryman should be directed to his feet. Even relatively slight defects of the feet are the cause of the absolute rejection of a recruit, and it is all the more essential that, once enlisted, this most important detail for the foot soldier should be thoroughly enforced. Regular inspection of the feet, either by the surgeon or by the company officer under the supervision of the medical officer, must be made. The persistent bathing of the feet and early attention to all blisters, corns, and chafed areas must be insisted upon. A very trivial blister or corn on the sole of the foot will disqualify and render a charge of the best soldiers. Supervision of the shoes, of the character and cleanliness of the stockings are therefore of very essential import for the military medical man.

The skin of the men must be looked after, all diseases due to vermin must be detected early and efficiently quarantined, or a whole company may become infected and perhaps disqualified for service. Officers must see that the men bathe as often as the conditions of service permit. Soiled underclothing must not be worn. The changes in uniform in accordance with climatic variations are customarily regulated by the commanding officer under the advice of the senior surgeon; thus the military medical man becomes, in an important way, a weather prophet.

It is very important that the soldiers' teeth remain in good condition; poor teeth mean poor mastication and consequent deficient digestion and absorption of food. Underfed soldiers are inefficient; therefore the military medical man must act as dentist and not only advise but see that his advice is acted upon.

Second in importance to the personal hygiene is the supervision of the food; the military medical man must be also an expert grocer and butcher. It is his duty to pass on the quality of the food, on its preparation, and even on the manner in which it is served; he must be an efficient cook and head waiter. How many of you know just exactly what constitutes a good cut of beef, just how beans should be cooked, and under what geographical and climatic conditions this or that food is to be issued or rejected? The military medical man must be fully acquainted with all these questions, and he must be prompt in his decisions, for more than the welfare of his men depends on it; perhaps even the loss of a battle or of a cause.

Even in civil life I think that the importance of the drinking and cooking water is fully appreciated. Nearly all the serious epidemic camp diseases, as typhoid, cholera, dysentery, are, at least at times, water-borne. With all this we are familiar, but in camp at times impure water is all that is available. Of course, boiling it renders it safe, but though it is not always easy in civil life to see that our clients do this, if they do not in military life it is the medical officer who is blamed. On the other hand, it is under his recommendations that guards may be posted

over suspicious water supplies and all the water available is directly under his absolute military control.

The disposal of the waste, especially of the human excreta, is the subject fully appreciated in civil practice. I shall therefore but mention it, for even under the most disadvantageous conditions the medical officer is competent to cope with this perhaps even more efficiently than is his civil colleague whose experience in camp life and its conditions may be limited. Relatively little attention is devoted in civil life to the disposal of the urine, and yet Vaughn has shown that typhoid, cholera, and doubtless other diseases are commonly disseminated in camp life by the urine. Special orders in regard to the disposal of this fluid must be not only published but most rigidly enforced. In civil life a doctor is rarely consulted as to the disposal of horse manure, but in regimental camps this becomes a matter of great hygienic value, for flies breed chiefly in this material, and flies disseminate throughout camps typhoid, dysentery, and cholera. Not only must the breeding of flies be prevented, but that of mosquitos as well. The regimental doctor of this century is expected to be an expert entomologist; he must be able to distinguish the anopheles and the stegomia—not only this, but it is his duty to see that their breeding spots are ferreted out and eradicated. He must see that all patients with malaria or yellow fever are carefully screened with insect-proof web so that no mosquitos may bite them and thus transmit the disease to others. Is there any hospital in New York City where the ward patients are thus protected from malarial cases in the same room?

The venereal problem, so troublesome in civil practice, is even more so in the military, where gonorrhea and syphilis may cause the loss of a battle or perhaps determine the fate of a whole nation. As perhaps some of you know, the old Greeks coped with this problem in a most efficient way. Modern conceptions of morality prevent this with us, but I have heard it whispered that our brothers of the regular services when far enough distant from the various meddlesome organizations of modern society find also very effective means for eradicating this extremely serious difficulty. Quarantine of these patients in the regular service is effectively carried out, but in militia camps this is a matter of the greatest difficulty and under present conditions largely beyond our control. All that the medical officer can do is to advise, and it has been my experience both with line officers and with enlisted men that the counsels of the medical officer receive every respect and attention.

Many of the important duties involved in the selection of camp sites, their hygienic control and policing fall among the duties of the medical officers; this is a great study in itself and here the medical man becomes by turns the engineer, chemist, and military commander.

I have of course only very briefly suggested certain of the duties of the regimental medical officer in regard to the hygiene of his command. All may be briefly summarized in the statement that it is his duty to see that at all times all his command is physically efficient and prepared for the firing line. Ten years' study of these problems in the national guard service has made me extremely modest in these matters and very respectful of the knowledge possessed by the average medical officer of our regular services. None the less, I fully believe that should war break out, under the present efficient management of the Medical Department of the National Guard in New York, the camps of the New York State troops would be found relatively free from typhoid, dysentery, and the other epidemic diseases which have in the past been our chief cause of fatalities and military failures.

I have presented to you a very few of the many subjects which make this side of military science interesting to the medical man; if I have interested some of you sufficiently to make you feel that it is worth your while, I am content, and, in the words of St. Paul, I invite you to "Come over into Macedonia and help us."

44 West Ninth Street.

INSTRUCTION OF THE HOSPITAL CORPS.

By EDMUND PRINCE FOWLER, M.D.,
NEW YORK.
SERGEANT FIRST CLASS, SEVENTH REGIMENT, N. G. N. Y.

The work of the hospital corps necessitates instruction in more varied and diverse fields than that of any other department of the army, and as the success of a campaign depends largely upon the mental and bodily health of the troops engaged, the work of the medical department is of fundamental importance. To be competent, the men must be thoroughly versed and drilled, not only in the drill regulations and outlines of first aid, but in horsemanship, cooking, nursing, hygiene, sanitary matters, etc.

The general principles, school of the soldier, setting up exercises, steps and marching, are best learned by drilling with the companies of the command to which the corps is attached, for one of the prime requisites in hospital corps work is to become thoroughly acquainted with the organization, methods, and practices of the troops with whom one's lot is cast. The school of the detachment, litter drill, handling of the wounded with and without litters, the use of the ambulance, travois, horses, and the hospital and shelter tents can be taught at the regular drills of the detachment. Lectures on and practice in first aid, particularly the use of the first aid packet, the use and improvision of litters, bandages, dressings, splints and slings must be regularly held, and the men should be required to demonstrate these to the troops. This will better fit them for their duties and enable them to become, in case of necessity, competent instructors to the enlisted men of the command.

One important function of the hospital corps is to keep the surgeon in command constantly cognizant of the hygienic and sanitary conditions under his supervision, and of the thoroughness and promptness with which his orders have been carried out. In other words, to act as sanitary police.

In time of peace the hospital corps in the guard are at a great disadvantage in regard to obtaining satisfactory instruction in the care and treatment of the sick and wounded, there being practically none to care for. Imagine a hospital without patients whose personnel consisted of several physicians and surgeons little versed in management and ignorant of the methods of ordering, obtaining, or distributing medical, surgical, food, and other supplies. Imagine under them a few nurses, but many orderlies and helpers whose only information regarding their duties had been obtained from books and weekly drills. Imagine, further, that the ambulance drivers, cooks, and servants had real instruction in their work once in two

years, and that few actual patients were cared for. If this hospital outfit were suddenly sent to a distant city in which there had occurred a terrible disaster what would they accomplish, and how would their organization and training fit them for the emergency? If war should occur in the near future, many hospital corps would present a picture hardly less deplorable than the above, and the most learned surgeons would find themselves so handicapped that their services would be of little avail under the circumstances. The surgeon from civil life, untrained in army methods, can be of use in the army only in the home or base hospitals, or on certain advisory boards.

Fortunately, the work of building up a satisfactory corps in the national guard is making headway, and we hope within a year or so to be prepared, at least in skeleton formation, for the inevitable. In all departments of human endeavor men differ greatly in their training and fitness for specific duties, and we should realize this and assign them accordingly. I believe the only satisfactory solution of the problem in the national guard is to enlist in our hospital corps a sufficient number of physicians, pharmacists, and trained nurses (about 25 per cent. of the corps) so that in time of war these may give to their country not only their services as men, but their services as soldiers disciplined in the work they are called upon to perform, and especially as trained attendants of the sick and injured.

The basis of the corps is the litter squad, consisting of two men, one of whom is experienced and is in command. If, then, even a small detachment be well instructed, we have a solid basis for quickly instructing the green bearers in their duties and of thus enlarging the corps to the requisite number. Most men can be quickly taught to carry the wounded, but it requires constant practice in the sick room to become a competent nurse. Therefore, the trained nurses should be so distributed that they may be used in nursing, namely, at the dressing and ambulance stations at the field hospitals and, if a sufficient number be obtainable, in command of litter squads. The place for the female nurse is in the base or home hospitals, and not with the fighting line.

The army hospital corps pouch contains one bottle spirits of aromatic ammonia; sterile gauze bandages; one case with pins, scissors, dressing forceps; one jack-knife with saw and corkscrew blades; one rubber bandage; one wire splint, and eight first-aid packets. It is simple, compact, and ample for most emergencies. This pouch is carried by the privates in the hospital corps, and every man in a command should be provided with a first aid packet, and instruction in its use should be imparted by lectures and demonstrations, the men being required to practice bandaging and applying dressings and compresses to the different parts of the body.

The first aid packets contain two antiseptic compresses of sublimated gauze in oiled paper, one antiseptic bandage of sublimated cambric with safety pins, and one triangular bandage with safety pins, and mode of application illustrated on same. Directions for using the compresses are printed on the packet. I quote from "Outlines of First Aid," p. 146:

"As most of the first-aid work in war under present conditions will be done by the individual soldier acting alone, and not by a squad of two or more men, it is important that his training should be largely individual and such as will develop self-reliance and resourcefulness. The object of any teaching upon first aid, or early assistance of the injured or sick, is not only to enable one person to help another, but in some measure to help himself. The purpose of these directions is to show how this may be done with simple means and by simple methods. It is a mistake to think that you must know many things to be helpful, but you must understand a few things clearly in order to assist the patient in the severer cases until he can be seen by the surgeon or those who are thoroughly trained. In ordinary cases what you can do may often be all that is necessary."

The orderly pouches are larger than the hospital corps pouches and contain a more elaborate outfit of medicines and appliances.

In service the injured must be promptly reached and a temporary dressing applied to their wounds. The patient is carried to the nearest dressing station. A diagnosis tag is attached to his clothing, and if necessary the wound is redressed. Often the first dressing is all that is needed for several days, and the importance of making this dressing carefully cannot be too strongly insisted upon. From the dressing stations the wounded are carried to the ambulance stations (unless their condition prohibits this) and thence transferred to the field hospital or further to the rear. As soon as practicable, all patients who cannot return to duty are shipped to the hospitals at the base of the army or at home.

In the guard, the instruction must be carefully planned, so that every year the whole subject may be systematically rehearsed. It is unwise to demand too much time of the men, as their value to the State and nation depends not only on their ability as soldiers in the corps, but as self-supporting members of the community. If in their enthusiasm they are led to neglect their business and the support of their families, they cease to be of use in the national guard, as the State will not supply them their daily bread. Membership in the National Guard Hospital Corps is of real benefit. It teaches the men many things which are useful in every-day life, and prepares them for emergencies. It promotes good fellowship, esprit de corps, and the enjoyment concomitant with these.

In the Seventh Regiment all the sergeants in the Hospital Corps are physicians, and the other enlisted men are trained nurses. Three of my men have kindly offered their services that I might demonstrate to you some of our methods of transporting the wounded and some of the simpler ways of improvising splints, slings, etc. As splints we can use rifles, leggins, straw, sticks, etc. Litters may be improvised from rifles and blankets, rifles and overcoats, etc., camp cots, shutters, doors, ladders, etc. (all padded); sacks or bags with poles, and crosspieces to keep them apart; bed ticks, matting, carpets, framework of poles or cross sticks, or, better still, ropes and rawhides. For bedding use weeds, hay, straw, leafy twigs, covered or not with blanket.

57 West Seventy-sixth Street.

Comparative Value of Different Methods of Hebotomy.—Cyrille Jeannin considers hebotomy a real advance over symphysectomy. As to the best method of performing the operation, he prefers the open method, which allows of prevention of wounds of the bladder, better hemostasis, and better drainage. The incision of Gigli is too far inward, that of Van der Velde too far outward, the median incision of Codereini being the best. In the subcutaneous method we have the danger of wounding the bladder, and that of thrombosis and infection.—*La Presse Médicale*

MEDICAL EDUCATION IN FRANCE AND GERMANY.*

By EUGENE ST. JACQUES, A.B., M.D.,

MONTREAL, CANADA.

ADJUNCT-PROFESSOR OF CLINICAL SURGERY, LAVAL UNIVERSITY.

The foreigner who travels through Germany, and particularly he who resides for some time in the country, cannot but be impressed with three things: The ever-present military, the countless chimneys of its manufactories, testifying to its ever-increasing industrial activity, and last, but not least, the importance that higher education holds in the life of the country.

Should he examine an educational map of the country, he would find it studded with 22 dots, representing as many universities. Should he consult the General University Calendar, he would learn that they are attended by 33,000 students, divided into: Philosophy and Letters, 15,000; Law, 12,000; Medicine, 7,000; Theology, 4,000.

How has it come to be that 22 universities were founded, could develop and attain as a whole the world-wide reputation which attaches, as we all know, to the German universities? The German Empire is only of yesterday. Each component part had developed independently. Kings and kinglets, dukes and princes, had for centuries past rivalled one another, in the military field. Men gradually became more civilized and refined, and with the fourteenth century sprang that movement of renovation which swept over all of Europe. The spirit was beginning to muzzle the brutal instincts which had till then governed men, so to speak.

Italy was the first to awaken to the Renaissance, and the Universities of Bologna and Padua were the leaders in the regeneration of medicine. The school of Montpelier and Paris soon became famous, and Wenceslas, who had studied on the banks of the Seine, founded in 1348, on his return to Prague, the first university of the so-called German countries. Before the century ended the Universities of Vienna and Heidelberg were born.

From that time every king and prince, through ambition and jealousy of his neighbor, wanted to have a university of his own, who could outrival the others. So it came that with the opening of the Nineteenth century 22 universities could be found scattered from the Alps to the Baltic, and from the Elba to the Rhine.

Philosophy and law were everywhere leading, while medicine occupied only a very modest place. Sure to say, during the Eighteenth century the English had added to the knowledge left by Sydenham. Hunter the Argus-eyed, Cullen and Brown were then the propounders of medical thought. But our art was still in its infancy.

With the French anatomist, Bichat, medicine awakened at the opening of the Nineteenth century. He differentiated the tissues and called attention to the fact that the manifestation of disease were due to lesions of these different tissues. Dupuytren and Cruveillier continued his work and established gross pathological anatomy, whilst Laennec, Louis, and Grisolle were laying the foundations of our clinical methods. "All students flocked to Paris in the fourth decade," remarks Osler.

But soon the Vienna school came to pre-eminence. While Rokitansky explained the gross pathological lesions, Skoda was showing the relation between the symptoms and the lesions. Modern chemical methods were that day created.

Germany was soon to startle the medical world with Virchow's magnificent researches on cellular pathology, and carry the searching eye of science still further into the secrets of nature.

But glory is as unsteady as the goddess who distributes its laurels, and a few years had scarcely elapsed that the fickle goddess was again crossing the Rhine bringing the astonished and incredulous world to the school of Pasteur. Had these two nations only been the chosen ones as benefactors of suffering mankind, there might have been recrimination. And so it was that England was allotted also its large share. It was to be given to Lister to make modern surgery a possibility. And so nowadays, three great schools are at the helm, imparting to medicine its onward march toward a goal still far distant, but all the time leaving on its tread, instead of despair, relief and hope.

And now, if we give a closer consideration to matters educational, and particularly, medical, and inquire into the causes which have given to German universities such a world-wide influence, we cannot but be impressed with three factors, which stand out pre-eminently: The high standard of the professorial corps; the number and perfect equipment of its laboratories; the educational methods.

1. The Teaching Staff.—The general university organization consists of a central board or council, whose members are delegated by the different faculties. This council busies itself with things of interest to the general welfare of the university, while each faculty has, so to speak, a free hand to deal with its own affairs.

The first rung in the ladder to the professorship is the Privat-Dozent. The title is a rather easy one to obtain. It is not gained by competition, by concourse, but simply on presentation and discussion of a thesis before the faculty. The candidate moreover must have to his credit a number of medical essays or investigations.

Germany is the land of specialization. From the very day the young M. D. has his diploma, he must bend all his energies in one direction; his aim is and must be to become a specialist. So, from the start, his field is narrowed down; what he will lose in breadth he will gain in depth. The title of Privat-Dozent is only an official recognition that he is working toward professorship. It confers on him no absolute right nor obligation to lecture, nor any salary. But with the approval of the faculty he may at his own risk give public lectures, which students are at liberty to attend or not. Very often if he has already given proof of ability he will be officially charged with lecturing on special subjects. In short, this title is an encouragement to further work and investigation. The Privat-Dozent may remain such all his life and die a simple P. D., but if he is a man of teaching ability and investigating mind, opportunity lies open to him and he will climb the ladder.

Next to the Privat-Dozent is the Extraordinary Professor, which title is granted to very talented men, but does not yet make of them members of the Faculty.

Finally, how is a vacancy in a chair filled? Here lies one of the peculiarities of the German organization. The faculty is absolutely free in the choice of the successor, who must receive the sanction of the Minister of Public Instruction. They may choose

*Read before the Medico-Chirurgical Society of Montreal, Can.

him from among their ranks, or call him from another university, or even pick him from outside; what is wanted is the best, and best they have at at any cost. And so it was that Billroth, who was only a relatively young professor at the university of Zurich, but already drawing to his clinic students from the world over, was offered the clinical professorship in surgery at the university of Vienna. And so long as the old master was alive, Vienna was the German Mecca of surgeons, just as years later Bergmann and Mikulicz diverted strongly the tide towards Prussia—to Berlin and Breslau—and nearer to us, we find Garre called from Königsberg to succeed the lamented Mikulicz in Breslau, and Bier, of lumbar analgesia fame, invited from Hamburg to Bonn on the death of Schede, and more recently to succeed the lamented v. Bergmann in Berlin.

The faculty is free to choose its members where it pleases, but in return the students are at liberty to follow or not his lectures or clinics. And herein lies one of the causes of the success of the German professor, strange though it may appear. I well remember the days when we had choice between the medical clinics of Gebhardt, Senator, and v. Leyden, or Olshausen and Gusserow in gynecology, or Bergmann or Koenig in surgery, or, again, between the lectures of Virchow or Langerhans.

As the student in Germany pays only for such lectures or clinics as he chooses to attend, nine-tenths of such fees going to the teacher, the necessary corollary to all this is clearly obvious. One will follow only the man who is the best teacher, who is most practical, whose lectures are most instructive; the other will have students and income only so long as he pays attention to his duties and takes pains to make his clinics interesting in the full sense of the word. Carelessness and sluggish attendance on the part of the professor and unscientific teaching are things unknown in Germany, for he would lecture before empty benches ere the semester was at an end. And so it is that all the professors are active and energetic and few among them are old, in the Osler sense of the word.

Moreover, as the medical curriculum is to a certain extent the same through the land, it is possible for a student to study histology or pathological anatomy in Berlin, for example, bacteriology with Behring in Marburg, internal medicine with v. Leyden in Berlin or Schultz in Bonn, or gynecology with Olshausen in Berlin or Zweifel in Leipsic, or again, surgery with Bier in Berlin or Trendelenburg in Leipsic. And in fact the German student is to a certain extent a "Bohemian," going from one place to another, resembling the student of the Fifteenth and Sixteenth centuries, who roamed about from Bologna and Padua to Montpellier and Paris, or from Oxford to Vienna, according to the renown of the professors.

2. The second factor, as I said, to the fame of the German university is their *"splendid endowement and laboratory equipment."* The budget of public education in Germany is the highest of all countries, with the exception of the United States, where private enterprise has taken higher education in hand, and with what generosity we all know. In fact we must recognize that the German government is rather lavish about it, thinking rightly that the élite of the nation cannot be too well prepared and equipped, since sooner or later they will be the makers of the destiny of the country, be they jurists or philosophers, theologians or men of letters, engineers or physicians. I shall necessarily be brief on this matter, since I can speak only in a general way.

Every clinic has its own laboratories, and the two best installations I have seen of the kind in Germany are those of Bier and Trendelenburg. Not only has Trendelenburg pathological and bacteriological laboratories, cabinets of photography, microphotography, and radiography of his own, but also quite a considerable museum of pathological specimens just next to the clinical amphitheater. Moreover, a simple pressure on an electric button will bring down the window curtains and a special apparatus made by Zeiss—an epidiascope—will throw on the screen not only radiograms or lantern slides, but also any picture or design, or still better, the pathological specimen itself, magnified and preserving its natural coloring.

The pathological museum in Berlin, which was inaugurated on the fiftieth anniversary of Virchow's professorship, is probably the greatest institution of its kind in the world. All the specimens are mounted by the Kaiserling method, which, as we all know, allows the different tissues to retain their normal color.

3. The German methods I indicated as being the third factor. Teaching is not all in university work, and the faculty whose staff would be content with simply transmitting what tradition has delivered them would indeed be far from performing their duty. Modern science requires more of its priests. Not only must they know the past, but also look into the future, scrutinize the sphinx, and plough through untreaded land; in a word, the modern professor must be at the same time a teacher and an investigator. Investigation and teaching have at all times been the double aim of German universities, and much more so since science has renovated, modernized itself.

Laboratories are numerous and splendidly equipped all through the land. Physikalishen und Pathologishen Instituten stand out preeminently at every university, and in fact the strength of the German medical curriculum rests with the teaching of the so-called preparatory branches, physical and biological sciences, dissection and microscopical anatomy, pharmacy and bacteriology, what, in fact, corresponds to the preliminary scientific and intermediate examinations of the English programme. Each and every one of these branches is most thoroughly and practically taught to the German student, the foundation for the superstructure is nowhere better laid than in Germany. As for medicine proper, or pathology, there is one thing which stands out forcibly here, as in fact also in Vienna and Paris, viz., the little importance attached to theoretical teaching and to lecturing. This is reduced to the smallest possible quantity. But *en revanche* the German student must attend to clinical work, and in fact he spends his whole day in the hospital—let me be more precise, in the amphitheater. And here lies, in my opinion, one of the drawbacks, and an important one, of the German methods. The student has little if any ward work. Dispensary attendance and bedside instruction which hold, and rightly, such an important part in the English and American schools, are in Germany almost if not altogether neglected. The clinical work is done in the amphitheater, in presence of large audiences, one or two students being called down to read the clinical history of the patient which has been recorded by a qualified assistant before-

hand, the student is questioned before the class concerning the patient, and the lecture thus goes on. To sum up, the student has very little personal contact with the patient, no prolonged, nor repeated, nor daily contact with the sick, as he ought to have, as he is given in London and Paris, in Johns Hopkins and Harvard.

Conditions are different if we speak of post-graduate work, for then the physician who desires to specialize will take private lessons either personally or in small groups. These must, of course, be paid for, and in the long run would be too expensive for the students.

As regards post-graduate work, what are the facilities offered in Germany?

Twice a year, in the fall and at Easter, special and limited courses which cover nearly all the different fields of the healing art are given at the large universities. Such courses are given by the assistants generally. All the hospital material is used for clinical purposes and for the benefit of the doctors only, no student being admitted to such lectures, which cover a period of four or five weeks. Here again the greater part of the teaching is done at the amphitheater—though limited ward classes can also be arranged for. If one is desirious of doing special laboratory work, ample opportunities in that direction are offered all the year round, and he will receive a hearty welcome from the German master and find attentive and interested "coachers" in his assistants, for very reasonable fees.

The importance of advanced work is so well realized in Germany that a new school has just been established for the express purpose of post-graduate students. Prof. Witzel of the University of Bonn was the organizer and is the director of the new Institute. The professors are among the best of the land, and no money is being spared in order to have a model Institute. The clinics have opened with 800 beds to begin with, plans being made to increase the number to 1,200. Laboratories are of the best, most complete, and modern. The new Institute, situated in Düsseldorf on the Rhine, near Cologne, in a densely populated and industrial part of the country, has already attained quite a degree of fame.

Such are the organization and methods of the German universities and the facilities offered for medical work in the Kaiser's land.

And now let us cross the Rhine and examine things medical in France. We have seen that in Germany the universities, some of them centuries old, already existed independently scattered through the land. With the organization of the Empire followed the unification of the military system and soon the reorganization of higher education—it was a synthesis. In France it has been just the opposite—a "decentralization."

Up to some twenty years ago Paris was the great center of learning in France—as in fact it still remains to-day. But the Paris University was then the only very important one of the land. Medical schools and faculties of law, of letters, of philosophy had long existed scattered through the country. But there was no unification, the faculties were independent of one another, with no link to make a whole of these scattered parts. In 1885 a government decree organized universities in the larger cities besides Paris, by grouping the different faculties and schools. Napoleon had centered everything in Paris under his hand—now Paris was to give back some of its prestige and power. And so it is that to-day there exist through France sixteen universities, the best known of which are, besides Paris, Lyons, Bordeaux, Montpellier, Toulouse, Nancy, and Lille. If we total the number of students for medicine and law, letters and philosophy, we come to the respectable figures of 33,000, 14 per cent. of whom are strangers.

Let us look into the medical organization and see how things are conducted. I shall speak of Paris, being the most interesting and complete medical center in France.

The Hospitals.—There are thirty hospitals and all are under control of the city, whose hospital budget amounts every year to $8,000,000, which gives an average of $200,000 to $300,000 per hospital according to its size and importance. Their physicians and surgeons are appointed after competitive examinations. The first is eliminatory, with three sittings—two or three hours' duration for a written subject—the third is a clinical lecture which must last one hour. The second is definitive and nominative, consisting of a written consultation and a clinic of twenty minutes duration after a few minutes allowed for the examination of the patient.

Those elected will only be given charge of the ward work—no teaching.

The Teaching Staff.—This department is under exclusive control of the faculty, and every position must be obtained by competition. It begins early for the assistantship.

All assistants are students in France, be they externes or internes, dressing clerks or house physicians or surgeons, while in Germany they are full-fledged physicians. Let me add that the former are in no way inferior to the latter, as we shall presently see. To give an example how these 250 positions are sought for, let me say that for the 60 vacancies in 1,900, 600 candidates competed. These examinations are more severe than for the degree of M.D.—and as the position adds three more years of exclusive hospital work, these assistants are bound to know something when they take their degree of M.D.

The next step, in surgery, for example, is to compete for a position of demonstrator in anatomy, then for clinical assistantship, such positions being opened only to physicians of many years' standing. As the aspirant climbs, the concour or competition becomes more severe, and to become an agrégé requires knowledge and teaching abilities quite uncommon. The agrégé must specialize in one of three sections:—Biological Sciences, Medicine, Surgery, and Midwifery.

The following are the conditions of the concour: 1. Eliminatory; (*a*) the candidate must state orally what work he has done and investigations he has carried on. (*b*) After three hours' preparation he must give a lecture lasting forty-five minutes. (*c*) He must undergo a written examination on anatomy, physiology, and the physical sciences.

2. Decisive, consisting in (*a*) Laboratory exercises; (*b*) A one hour theoretical lecture; (*c*) A clinical lesson. It is evident that not only must the candidate be well learned and versed in the medical sciences, but he must have the talent of conveying what he knows in a clear and interesting form. And here is one of the characteristics of the French medical schools—the unsurpassed and rarely equalled talent of clinical exposition of its teachers.

These agrégés are appointed for nine years, after which, if in the meantime they have not climbed a step further, they lose title and privileges.

The professor is chosen, as in Germany, by the council of the faculty—either from among the agrégés or called from a sister university; the fittest to the position. The senate of the university and the minister of public education must and generally do approve of the nomination. En passant, let me note one of the peculiarities of the French system. There is to the professorship an "age limit," at which the professor must climb a step higher and be contented with an honorary degree. It is a strength to the faculty and one of the conditions of its effective and productive vitality.

And what about the student? This brings us to the teaching methods. Paris numbers 3,200 "registered medical students"—which does not include the great number of foreigners who, not registering to take the regular M.D. diploma, nevertheless come to Paris for post-graduate work. The medical curriculum extends from five years up. Natural sciences—the preliminary scientific examinations of the English curriculum—have already been attended to. Before beginning the study of medicine, the student must have his P.C.N. diploma (Physique, Chimie et Sciences Naturelles).

Part of the program is obligatory, the rest is not. Laboratory work and hospital attendance are obligatory; theoretical lectures are not. If we follow the student through his years of medical apprenticeship and glance over the program of the medical studies in France, we cannot but be impressed with the fact that, as regards the theoretical part, the student attends as he chooses. Theoretical lectures are given at the university, but do not in any way cover the whole subject. They are most thoroughly and most brilliantly given, but limited to certain fields. As we readily understand, the student is at liberty to attend these lectures or not—which are free to everybody. And so it is that the student must study at home his theory of medicine. In fact this is not peculiar to Paris alone, nor to the French schools, but is met with also in Germany, as I have already pointed out. What is aimed at abroad is practical work in all departments.

To the same degree as medicine was principally a theoretical art up to a century ago or so, so is it looked upon nowadays as a practical science; its secrets are to be learned very little from books. Its foundations must be laid in the laboratories of physical and natural sciences. There, and there only, these are learned thoroughly—just as pathology is learned at the hospital. And the more a medical school is progressive, the more we see the number of its theoretical lectures diminish, while larger and larger grows yearly the time devoted to work in the laboratories and in the hospital.

What has been propounded again and again by Osler, whose experience in teaching is not to be minimized, is: "Take the student from the lecture room; take him from the amphitheater; put him in the laboratories; put him in the out-patient department; put him in the wards. The work of the third and fourth year should be taken out of the medical school entirely and transferred to the hospital." But Prof. Osler is not original in his saying, for more than a score of years ago that most astute of minds, Oliver Wendell Holmes, had said: "The most essential part of a student's instruction is obtained, as I believe, not in the lecture room, but at the bedside; for nothing seen there is lost." Still a hundred years before, Abernethy wrote: "The hospital is the only proper college in which to rear a true disciple of Æsculapius."

Facilities for dissection are simply perfect in Paris. Anatomy is taught in the dissecting room by a staff of twenty-four assistants. Operative medicine is one of the great points of the Paris school, students being grouped in squads of ninety, in turn subdivided, and the demonstrations on the cadaver being completed by colored drawings on the walls, done by the best artists familiar with anatomy.

Where the French methods stand unsurpassed and I think unequaled are for hospital work. The nearest to them I have seen is in some of the London schools and more particularly at the University College Hospital and at Johns Hopkins. All the medical students from the second year up have to attend the hospital; this is obligatory. In groups of fifteen or twenty they are attached to the different services, where they must be in attendance every morning—the roll call testifying to their presence. Their work is to write down the clinical history of the patients and examine them, do the dressings, and lend a helping hand in all minor and practical operations. They must give at least twenty months—three and one-half semesters—to such work. The first twelve months to general medicine and surgery alternately, three months in a maternity, and the balance to the specialties of their choice.

Three days a week, the physician or surgeon, as the case may be, goes through the ward with his assistants—internes, externes, and the students—examines the new patients and gives bedside instruction. On the other days, after a rapid visit to the wards, he goes to the amphitheater where he lectures on a given subject, one or two patients of the wards furnishing the material for the clinic. They are generally brought before the class, the history of the case being gone over, the differential diagnosis made, and then the whole question is expounded.

Now I would refer to some of the things which strike more forcibly the visitor to the medical school of Paris.

1. All tuition is free, nothing to pay, only a fee by the student when he goes up for examination. All visitors are welcome to the lectures and clinics. Special group classes are organized for advance work in all departments; for such private courses very moderate fees are now being charged.

2. I would call your attention to this point: the free access to the patients in the wards. The simple presentation of one's card will make one welcome to the service where one will be at liberty to examine cases when the chief makes his visits and also between times if desired.

3. I would recall what I have already mentioned in regard to the French professor as a clinician. He is a born brilliant speaker; his facility of elocution only equals his clearness of conception—the "charming lucidity" of which Osler speaks as his characteristic.

But the teaching of a medical school whose aim is to become a factor in the international medical movement must not be confined exclusively to undergraduates. It must busy itself with advanced work for post-graduates. And here Paris offers great advantages. Let us examine some of them.

Are there any specialties in medicine in which Paris takes the lead? Yes, surely, as in others Berlin and Vienna are superior. I know of no school yet which eclipses all others on the whole line—be it London or Edinburgh, Berlin or Leipsic, Vienna or Munich, Paris or Lyons.

Let us see in what branches Paris excels.

In the study of *skin diseases*, Paris is of all schools the leader. The St. Louis Hospital with its 1,200 beds and its out-door department, where from 9 A.M to 3 or 4 P.M. one can witness a continuous flow of humanity (I recollect the number of 283 patients one morning), offers unrivalled opportunities. Next to the out-door department is the museum with the world-known Baretta collections of wax models of skin diseases in the natural coloring. And this is only the most important skin clinic in Paris, as there are many other smaller ones.

As for the study of *nervous diseases* the Salpêtrière Hospital with its 3,000 beds is too well known for it to be necessary for me to dwell on it. Profs. Raymond and Déjerine, pupils of the great Charcot, uphold the traditions of the school, while Dr. Alquier in charge of the laboratory of pathological anatomy will always welcome anyone desirous of pursuing advanced work in this special line. Prof. Ballet holds twice a week clinical lectures at the St. Anne Hospital, which are always eagerly sought for by specialists.

When I speak of the study of *genitourinary diseases*, the names of Prof. Guyon and of Prof. Albarran and his clinic of the Necker Hospital will at once come to the mind of those interested in this special branch. Though Berlin has its Casper and Nitze, Paris outrivals others with the facilities it offers in this line. Not that more of these diseases are met with here—all large European cities are more or less alike on this point and none holds yet a diploma for virtue. But Paris has the best organization and Albarran's clinical lectures are as well sought for by the specialist as were those of the great Thompson. The material here is ample and the clinics given twice a week, before operations are performed in the presence of the class, are never purely theoretical as I have seen them at some of Berlin's most celebrated clinics, for lack of patients. Attached to the service is an interesting museum and a perfectly equipped laboratory where such men as Prof. Albarran and Legueu have made their research work and where one would find Prof. Motz, the pathologist of a score of years, coaching specialists in some research work. Next to the Necker Hospital, and secondary to it in importance, is the genitourinary department of the Lariboisière Hospital under the direction of Hartmann.

If I should speak of *surgery*, Paris stands second to none. Dissection facilities are all that could be wished for. Then twice a year, in the spring and in the fall, series of surgical technique exercises covering all the specialties of surgery are arranged for, under the direction of Profs. Segond and Hartmann, where every operation is repeated on the cadaver by those taking the course, for which a very nominal fee is asked. Let us moreover recall the daily visits to the wards, the clinical teaching in the amphitheater and the possibility of seeing the operative work close by the operating table—all these are facilities as great as one can wish for.

In *bacteriology*, the Pasteur Institute offers once a year a four-months' course, where everything in this line is taught and practical exercises constitute the main part of the teaching. Besides, should any one be desirious of pursuing special research work, he will always find a ready welcome from some of the directors of the Institute, Roux, Metchnikoff, Borel, or others.

In the *head specialities*—eye, ear, nose, and throat—it would be hard to shake off anything of the luster of the Vienna school. Suffice it to say, nevertheless, that the specialist will find his time amply repaid by a stay, even a long one, in Paris, which offers more and more every year great facilities for *personal work* in this special line.

And now were I to draw conclusions in the form of comparison, I would thus tabulate my final remarks.

Laboratories are more numerous and more completely equipped in Germany—the government being more lavish.

Then again *research work* is extensively carried on at every German university. Germany seems to be the land of *investigation* in the scientific field. Not that other countries are inactive in this direction, but they do not carry it on such an extensive scale.

Nevertheless there are two points where Paris surely stands equal to any other rival, not to say more—these are *dissection* and *bacteriology*.

As for *clinical facilities* they are superior in France—for the teaching is of a higher grade and then the daily access to the wards and patients gives it a most practical character and allows of more personal work.

Now as regards *post-graduate work*, it is more practically organized in Germany—but from a certain point of view—I allude to the vacation courses. Should a physician from the country or from a foreign land have only a few weeks to spare, he can run to Berlin in October or April, sure of finding during four weeks or so courses in clinical lectures covering every branch of medicine. This method of post-graduate work—for *men in a hurry*—is not yet so perfectly, so completely organized in France as in Germany—though immense strides have been made in that direction of late years. But what already exists in that line is more practical than in Germany, because it rest on *ward work, on personal contact* with the patient, and not purely on simple amphitheater demonstration.

As to the *future specialist* who must give many months, many years to preparatory work, Paris offers unsurpassed advantages and unrivalled facilities, particularly in *skin*, *genitourinary* and *nervous diseases*, and in *surgery*.

29 Sherbrook Street West.

TRAUMATIC HYSTERIA IN ITS RELATION TO SURGERY.*

By BRADFORD C. LOVELAND, M.D.,

SYRACUSE, N. Y.

NEUROLOGIST TO THE HOSPITAL OF THE GOOD SHEPHERD.

Anyone who has observed traumatic hysteria or neurasthenia in its various aspects cannot fail to have been impressed by the large variety of accidents which have been held responsible for the trouble, and one will be equally impressed by the entire lack of relation between the severity of the injury sustained and the nervous results. It often seems, indeed, as if the nervous after effects were in almost inverse proportion to the severity of the injury; that is, that a severe traumatism seldom results in nervous trouble, while a comparatively slight accident is often followed by very profound and persistent nervous symptoms. I do not say that this is exactly the case; in fact, I do not think the severity of the injury has any definite relation to the nerv-

*Read before the Syracuse Academy of Medicine, April 20, 1909.

ous after effects; but these seem to depend more on the individual peculiarity of the person who happens to suffer from the accident or traumatism, and the psychic environment into which he is thrown. Thus we see traumatic hysteria develop after severe injuries, and after accidents where the trauma was almost nothing; and in fact we sometimes find the same condition induced where the exciting cause was merely a fright in anticipation of an accident that never occurred. In other words, a pure psychic insult may initiate all that train of symptoms which are usually attributed to traumatism.

The question then arises: Can these cases of traumatic hysteria be prevented? or, when early recognized, can they be aborted? The answer is yes, to a degree. Of course, prevention depends on the recognition of the type of person who is likely to become a victim of the trouble whenever opportunity offers. This is manifestly impossible where the traumatism is a pure accident, such as a shakeup in a trolley or railroad collision, but the physician is supposed to know his patent's characteristics in a way very different from the knowledge a trolley company could possibly have of its patrons, and he should be on the alert for such possibilities. My attention was first called to this subject some sixteen years ago, when I was consulted by a Mr. J. H. B., of Hughesville, Pa., a prosperous furniture manufacturer, who had recently been operated on in Philadelphia for the removal of enlarged turbinated bones. He had completely collapsed nervously, and came to the sanitarium where I then was practising in a special car, attended by his physician, a trained nurse, and his whole family, for he would hardly let one of them out of his sight fearing that he was in imminent danger of death. All this distressing sequel to his slight operation he attributed to too much cocaine.

My next reminder came a short time later, in the case of Mr. W. H. G. of this city. He had recently passed through a similar operation for some nasal or throat trouble, but was not quite so badly affected nervously, though he had given up work. Here, again, cocaine received the blame. Recoveries occurred in both cases, though rather slowly. About fourteen years ago I had under my care also two cases following removal of the hemorrhoidal area, and cocaine bore no relation to either as a general anesthetic was used in both. Of these one was a man operated on in New York, the other a woman operated on in Chicago. Both operations were done by eminent surgeons, and were surgically successes, but the nervous results were among the most profound I have ever seen in this class of cases, and were months in recovering.

While preparing this paper I have had an opportunity to collect the cases from only one-half my notes, but I find in that half five cases of hysteria or neurasthenia following some distinctly surgical procedure which bore the same relation to the nervous trouble that accidents do to the ordinary traumatic hysteria. Three of these occurred after major operations, one after *x*-ray treatment for a rodent ulcer, and one after labor in which instruments were used. All these cases were surgically successful, but the patients were worse off with the nervous state than they were with the surgical condition. No one would think it just to hold a corporation responsible for the full extent of disability caused by traumatic hysteria following an accident in which an employee or passenger is hurt, and no one would think a surgeon responsible for the neurasthenic results which may follow his operations. Yet it is well to be forewarned and thereby forearmed so that the first signs of nervous trouble shall receive prompt and appropriate attention before the condition becomes chronic.

I will report two of my cases in considerable detail, as there is something of interest in each.

Case I.—Miss M. C. H. was referred to me by Dr. A. B. Miller on Sept. 8, 1902. He had operated on her for a tumor and a diseased appendix in 1899. She had also had her tonsils and uvula amputated, but this was some time previous to her abdominal operation. She had made a good recovery from the surgical procedure, but soon began to complain of vague nervous symptoms, such as vertigo, weakness, and pain in the back of the neck extending up into the head. She had been fitted with glasses, and various kinds of treatment employed with negative results. My notes taken at the time of first examination describe a woman 48 years of age, short, stocky, slow of speech, and apparently slow of perception. The eyes were sensitive to light, and the pupils reacted normally. There was a slight excess of both the ankle and knee reflexes. The station was normal, the weight was 122 pounds. The stomach was slightly prolapsed. There was tenderness over a great portion of the muscular territory of the body. She was especially hyperesthetic over the spine nearly its entire length, over the lumbar muscles, and over the lower abdomen. A firm scar in the median line marked the site of the operation. Her bowels were constipated, the bladder irritable, but the urine was normal. Her pulse was from 80 to 90, and the temperature normal. She complained of gas and burning in the stomach, worse at night. She had a good appetite and ate heartily. She was advised to come into the hospital where she could be under closer observation, as she lived out in the country. She came in for two weeks, during which time it was observed that she suffered from astasia abasia. She would stand or walk correctly under the direct influence of my command, but when attempting to do the same thing alone she not infrequently would begin to fall backward, and, in trying to save herself, would run backward till she was stopped by a wall or actually fell. She improved very nicely while under the inspiration of frequent visits and powerful psychic stimulation, but drifted back into the old condition and gradually grew worse, when she abandoned regular treatment.

For the past six years she has called a doctor only when some acute trouble like influenza or bronchitis supervened, or sent someone occasionally for medicine for her muscular pains, which she calls rheumatism. Her general condition has stayed about the same except that she has grown quite stout. On Sept. 10, 1908, I took occasion to make another careful study of her condition and found all the reflexes normal, with possibly a slightly exaggerated knee jerk. The station was normal. The pupils reacted normally to light, though the patient kept her eyes shut much of the time. She complained of much pain of a muscular nature, was apparently very helpless, often falling, and occasionally hurting herself. She got up from a chair or the bed very slowly, and a relatively long time seemed to elapse after she was asked to do something before she began to make a motion, as though it took an unusual time for her mental impulse to reach her muscles. She showed a grip by the dynamometer of 27 in the right hand and 26 in the left, which is

about two-thirds that of the average woman, but she acted much weaker than that would indicate. She had become very dependent on the woman with whom she lives to help her dress and walk, and, while she had grown stout, and ate heartily, she did so very slowly and often spilled her food. There seemed to be no decision about her movements. Now, with all this, when spoken to sharply so as to rouse her to effort, she could do much better than I have described; in fact, could stoop over and pick up something from the floor, or walk or stand with eyes open or shut without falling. I have long been convinced that hers was a case of traumatic hysteria, and the pity is that there seemed no way by which she could be held to discipline long enough to recover. The only thing which could confuse the diagnosis was the possibility of multiple sclerosis, which can be excluded by the condition of her eyes and the way she responds to strong psychic stimulation.

Case II.—Mr. G. F. H., 63 years of age, consulted me on Feb. 5, 1904. He had been a dry goods salesman for more than thirty years. Twenty-eight years ago he had a tape worm, and the treatment for this was followed by a severe attack of insomnia from which he took months to recover. For several years he had suffered from a rodent ulcer on his head, and recently one had broken out on his left cheek, apparently resulting from a cut by a barber while shaving him. When he consulted me he had recently completed a course of *x*-ray treatment which had been successful in healing the ulcers, but he had collapsed nervously, and had been under treatment for his nerves for about three weeks. The conversation he heard in the course of his *x*-ray treatments had brought the subject of cancer into his mind, and when I first saw him he imagined he had cancers inside as well as out, and that he was doomed to a horrible death. This fear so wrought on his mind that he could neither sleep nor eat, and he had no power to concentrate his mind on his work, and had been given an indefinite vacation. It required about four months to get him back into the habit of sleeping and reestablish his judgment and self-control so that he could take up his work again, instead of daily imagining himself dying from cancer. He has remained well and at work up to the present time, though the ulcer on his head has opened again, but he prefers the ulcer to the danger he fears from more *x*-ray treatment. In this last case it seems probable that if his nervous temperament had been recognized, as it could have been by a study of his history as well as his present condition, the nervous results of his *x*-ray treatment might have been avoided, much to the comfort of the patient as well as to the credit of the practice of medicine.

In regard to judging of one's liability to hysterical developments, it may be said that, like the art of diagnosis in general, beside the art of careful observation, and a judicial mind, there is also a place for that sort of instinctive power we call intuition, which may be of great service in arriving at a conclusion. I do not mean that one should depend on intuitive impressions, but I do mean that such impressions should be cultivated and considered of sufficient importance to be investigated.

In conclusion, I may say that the cases referred to in this paper represent only a small portion of the observations made on this subject, but they are sufficient to bring the subject before you for consideration. There has been no attempt made in this paper to advocate any particular method of treating hysteria, traumatic or otherwise, or to describe the treatment employed in the cases mentioned, the object of the paper being simply to call attention to the not infrequent relation that exists between surgical operations and hysteria of the traumatic type.

Fayette Park.

THE HYGIENE OF THE AIR PASSAGES.

By ADONIRAM B. JUDSON, M.D.,

NEW YORK.

The impulse to clear an obstructed air passage is perfectly natural, but it is well to give to the subject a brief critical consideration. When air fails to pass freely it is usually because the passage is narrowed by congestion and swelling of its lining membrane. But a person thus affected is apt to think that the trouble is caused by an obstruction which must be removed by forcing through the tube a column of air under pressure. He therefore either coughs, clears his throat, or blows his nose.

The facts are about as follows. An extra supply of blood is summoned to resist an invading foe, and irritation, swelling and secretion are incidents of the ensuing conflict. It may be said that irritation sounds the alarm, swelling indicates the presence of reinforcements, and secretion provides a covered way under which the affected part returns to a normal condition. The removal of mucus by the successful application of a blast of air does not justify the effort made, but really indicates that a natural protection has been surrendered. A similar situation is seen in the case of a cutaneous abrasion. It would not be good practice to wipe the part by the frequent application of a brush. It would be better to leave it untouched until healing takes place under the protective coat which inflammatory action has brought and spread over the affected part. When the throat is sore interference aggravates the irritation and the irritation in turn prompts further interference, forming a "vicious circle," which calls for the exercise of reason and self-control. Excessive secretion induced by repeated muscular effort does not prove that the case is a severe one and that action was justifiable. It indicates rather that inflammation and its products have been increased by ill-advised exertion. It is better to omit trying to remove obstructions which do not exist, and to apply if necessary for professional advice. When the surface is visible, it is seen to be reddened like the membrane in conjunctivitis, which produces a sensation like that caused by the presence of a grain of sand, when the patient is told not to rub the eye, recalling the sapient admonition not to rub the eye except with the elbow.

The mechanics of clearing the air passages have not received much attention. It is believed that a brief review of the facts will show that it is desirable to omit so far as is practicable customary efforts to obtain relief. The muscles brought into action are among the strongest in the body. They are the great expulsive groups of the chest and abdomen, capable of acting with extreme violence. In *clearing the throat*, the glottis is contracted and the rush of air displaces mucus that may have burdened the vocal cords. This action may be necessary after prolonged vocalization, but it easily becomes an obnoxious habit.

In *blowing the nose*, a column of air is applied under pressure for the removal of mucus from the nasal passages. This also is necessary at times, but

it is an action to be avoided if possible. It may be objected that failure to act leaves the face unclean. The removal of what appears on the surface calls for attention in any case, and occasionally, as in acute catarrh and hay fever, the annoyance may be extreme. The best must then be done in a bad situation, in which it should be recalled that the less the air ducts are disturbed the less will be the discomfort and the shorter the road to recovery.

When a person has what is called a cold in the head it sometimes happens that the severity of the attack makes it almost impossible to breathe through the congested nasal passages. In such a crisis it is interesting to know that relief may be immediately obtained by making a forcible expiration and then ceasing to breathe for a fraction of a minute, when breathing through the nose becomes easy at once. The good effect may be prolonged by keeping the volume of respired air at the minimum. The relief may be explained by the statement that the congestion of the lining membrane is reduced by the withdrawal of venous blood into the depleted lungs.

To contract the habit of blowing the nose seems to be a sure way of converting an acute state into a chronic catarrh, which is evidently the result of unceasing efforts to keep the passages clear, in ignorance of the fact that recovery from either acute or chronic catarrh will surely follow intelligent expectation under proper advice and after exceptional watchfulness and considerable endurance of personal discomfort.

In *coughing*, the power of the expulsive muscles is displayed in severe compression alternating with sudden release and agitation of the whole respiratory apparatus, while the compressed air is driven through the tubes with violence which reminds one of the action of a steam pencil, wanting only the mordant agent to become an excoriating sand-blast. The custom of resorting to this form of violent exercise can surely be modified by intelligent effort. It is not easy to ignore laryngeal irritation and temptations to cough when the habit is fixed. Reform is a tedious process, because it takes longer to go up hill than down. Neither is it altogether frivolous to say that if you do not cough the first time you do not have any cough. Expectoration, when unavoidable, may be facilitated by assuming for a moment an attitude in which the direction of the air passage is changed from the vertical to a downward inclination, when gravitation and a slight effort provide a harmless exit. In such straits quadrupeds have an advantage with their inclined windpipes, as was seen during the epizootic which visited American horses in 1872. A recent writer advises that drainage be promoted in certain forms of respiratory trouble by elevating the foot of the bed, and another seeks the same object by devising an ingenious inclined chair or table on which the patient lies prone. Since protection from local violence is part of a correct environment in lung disease, the omission of coughing is prescribed in the treatment of pulmonary tuberculosis.

It is generally known that *sneezing* may be prevented by pressing with the finger in the median line at the junction of the nose and upper lip. This stops the desire to sneeze by interfering with the nervous excitement which precipitates the spasm. Another way, novel perhaps, is to empty the lungs by a forcible expiration just before the muscular spasm is expected. The sneeze then takes place with the usual sensation, but there is very little noise and no column of air is sent through the passages as in the ordinary convulsion. The cap is snapped, in military phrase, but, as there is no charge in the barrel, there is no explosion. Although considerable violence attends a sneeze it is not likely that any harm results.

Ceasing to breathe by an effort of the will after a forcible expiration is a ready method of modifying the action of the heart. A weak pulse immediately becomes rapid, full, and strong, with peripheral vasomotor relaxation. This experiment cannot be continued long before the demand for air becomes distressing. By admitting air in small quantities, and thus gradually satisfying the want, the effect on the heart may be continued for some time without too great a demand on the endurance. It may be that full discussion has already been given to the questions prompted by this suggestion, which seems at the first glance to contain the germ of something useful and practical.

SKIN DISINFECTION WITH IODINE IN ABDOMINAL AND OTHER OPERATIONS.

By CHARLES JEWETT, M.D.,

BROOKLYN, N. Y.

THE iodine method of skin disinfection in preparing the abdomen for laparotomy has apparently attracted less attention than its importance deserves. It was first published by Grossich in the *Zentralblatt für Chirurgie* for Oct. 31, 1908. In the writer's work the results under iodine disinfection have shown a marked improvement over those of the usual soap and water scrubbing and mercurial or other commonly used antiseptic compresses.

While it is not possible by any method always to escape infection of skin wounds, in the writer's experience with iodine so far in clean cases no wound has broken down. Per primam healing has occurred uniformly.

The method obviously is equally applicable in preparation for practically all skin incisions. In a modified form doubtless it may assure equally good results in vaginal operations and upon other mucous surfaces.

The procedure as practised by Grossich is as follows: Some hours before operation the operation field is shaved dry and is then painted with a 10 or 12 per cent. tincture of iodine. No water or other liquid than the iodine tincture must be permitted to come in contact with the skin. The surface is covered with a dry sterile dressing. On the operating table shortly before the first incision the painting is repeated.

In my own work care is taken not to wound the skin in shaving and, unnecessarily, perhaps, the field has usually been cleansed carefully about twelve hours before the iodine preparation with soap and water and a gauze compress, shaved, dried, and protected with a dry sterile covering. The process is so simple that even an inexperienced nurse can scarcely go astray in carrying it out.

The tincture of iodine should be especially prepared for the purpose and should be kept in a bottle well stoppered with a rubber or glass stopper to maintain the due proportion of iodine.

It will be remembered that the tincture of iodine of the U. S. P., Revision of 1900, contains 7 per cent. of iodine and 5 per cent. of potassium iodide. The preparation which has been used by the writer differs from the official tincture only in the reduced proportion of alcohol.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, August 14, 1909.

LIFE INSURANCE AND PREVENTIVE MEDICINE.

THREE events of signal importance to the medical profession have recently been chronicled in the daily press. At the Convention of the Presidents of Life Insurance Companies, held a few months ago, it was generally agreed that the time had come when these companies could no longer regard with indifference the problems connected with public health, and the campaign, hitherto fought solely by the medical profession, for diminishing disease and increasing longevity. As a proposition of sound economic importance, this propaganda appealed with incisive logic to the business instincts of the heads of financial institutions. The postponement of the age of death would increase the income of these companies in two ways: first, by diminishing the number of death claims paid, and, second, through the general reduction in the rate of premiums, by increasing the number of those individuals who were willing or able to purchase life insurance. The benefits to the company and to the insured would obviously be mutual.

This discussion has already borne fruit. One of the largest companies has proposed to build a sanatorium for the treatment of tuberculosis among its extensive force of office and field employees, and among those of its policy-holders who care to avail themselves of this opportunity of getting cured or of having the disease arrested. Another powerful company has inaugurated a campaign of education among its policy-holders, through the dissemination of literature dealing with personal hygiene and preventive medicine. Moreover, it proposes, at no cost to the applicant, to furnish the policy-holder, whenever he may desire it, a complete physical examination, and whatever advice he may need to enable him to prevent or overcome any threatening or existing defect or disease. The former plan, involving the expenditure of funds for building and equipping sanatoria, has not been sanctioned by the Superintendent of Insurance of New York State, who has ruled that the present insurance laws do not permit such an investment of the funds of insurance companies. New legislation will doubtless, however, remove the technical restriction.

To the system of the education of policy-holders in the ways of right living there can be no legal objection. In view of the large number of individuals whose lives are insured, the inauguration of such a campaign of education by all companies would not fail to be of decided influence in improving the conditions of health not only among the large force of policy-holders, but also among the larger army of those who are closely related to them. The detection of incipient disease would necessarily suggest the proper hygienic and remedial measures. This effort toward diminishing the prevalence of disease and reducing mortality finds its perfect analogy in the measures taken by fire insurance companies in safeguarding property from fire, by means of a rigid inspection of buildings, and by the framing of rules regulating the proper form of fireproof construction, the storage of explosives, etc.

The influence of life insurance companies in uplifting the general health and mode of living has existed as a silent force from the very beginning of the inauguration of this institution. Countless have been those individuals who first learned of some existing defect, disease, or pathological tendency through the examination made when they applied for life insurance. How incalculable therefore must have been the efforts made to eradicate these defects and check these tendencies, which the applicants were impelled to make in order to qualify for a subsequent examination. The arresting of injurious habits of excessive indulgence in alcohol or tobacco, the avoidance of overwork, particularly the relaxing of the severe tension of business activities during and shortly after middle life, are familiar examples of some of the wholesome influences that life insurance examinations have created.

The era of preventive medicine has barely dawned. Statesmen are beginning to open their eyes to the vast importance of conserving the health of the nation in order to insure its civic integrity and permanence. The industrial world is not only no longer unwillingly yielding to wise laws designed to safeguard the health of the laboring classes, but is actually initiating, of its own volition, measures for improving the physical welfare, and therefore indirectly the industrial efficiency of the workers. The educational authorities are beginning to focus their attention upon the bodily health of the child, for without this, all efforts at mental training are worse than useless. The insurance interests, which have become an integral and indispensable part in the modern machinery of society, are merely falling in line with this universal tendency.

REGULATION OF MIDWIVES.

THE question of the proper care of the poor woman in pregnancy and labor is one of no little importance. In the country, where the family doctor must cover a number of square miles, it becomes impossible for him to attend all the midwifery cases that occur, and in those regions some woman with a limited acquaintance with the art of obstetrics is called in, in normal cases, to cut the cord and dispose of the placenta, when the doctor does not arrive in time. In the great congested centers, like New York, there is a large class of women of

foreign birth who have been accustomed to the more or less skilled services of the European midwife, who has in many instances had a fair training in obstetrics. It is impossible for these poor people to pay an adequate fee for the attendance of a physician, with the added expense of a woman to act as monthly nurse; she therefore turns to the midwife who makes a daily visit and gives whatever skilled or unskilled care the woman has. For these reasons we should have a class of skilled midwives in this country, who will be competent for attendance at normal labor cases, and will know when a physician should be called for further attendance. There has been some attempt made by the Health Department of this city to regulate the licensing of these women, and at present each woman who attends a case of labor must have a permit from the department, and that permit must be renewed each year. The applicant is not required to have undergone any specified course of instruction, but must present evidence of being twenty-one years of age and of good moral character, must be recommended by two physicians, and have attended at least twenty cases of labor under the superintendence of a regular physician, and have had the care of the mothers and of the infants. She must be clean and of healthy appearance.

Such are the regulations, however inadequate, under which labor is at present carried on among the poor. No wonder that not all labors terminate favorably for mother and child. Let us see what appears to be the actual status of these women as to possibilities of asepsis in care of labor cases. The Health Department rules describe the simple equipment which every midwife should carry with her, including antiseptic solutions, means for cleansing the nails, hands, and arms, before examination of a patient, douche apparatus, etc. These articles are to be ready at all times in a bag having a washable lining which can be sterilized by boiling. Actual examination of these bags has shown, however, that they are often old and dirty, and in no case examined did they have a washable lining. The bags contained practically no articles necessary for use. The prescribed articles would be collected from all parts of the midwife's establishment. In one case ergot was a part of the armamentarium, a drug which no midwife is allowed to carry. A clinical thermometer was missing in some cases. Whatever douche bag and nozzle might be found at the patient's house were used when needed. The solution for the child's eyes, a weak silver nitrate solution, and the medicine dropper were not in evidence. None of the articles found showed any signs of having been recently sterilized by boiling. Vaseline was usually carried in a bottle that had been repeatedly opened. It seems very doubtful whether the precautions for asepsis are ever carried out. Yet one woman had attended sixty cases in about six months. Under the circumstances it is not unreasonable on the part of the Health Department to insist upon better condition before giving a license.

The same question is even more pressing in France, where the midwife attends most cases of uncomplicated labor. V. Cocq, in the *Bulletin de la Société Belge de Gynécologie et d'Obstetrique*, for February 6, 1909, discusses this very matter. In France the midwife must have been graduated after a regular course of instruction, and must carry a similar equipment and observe similar rules to those prescribed in this city. The author, however, believes that the improvement necessary in the education of the midwife can be carried out only through attempts to raise the moral and mental status of the midwife. She must have a better preliminary education; she must be a woman of higher class to begin with; no one should be admitted to practise midwifery who has not had both theoretical and practical courses of instruction for at least two years in a recognized school of midwifery, connected with a maternity hospital; there should be greater care taken in the admission of candidates for these schools; they must be of better moral and intellectual caliber; they should have some means of income aside from their professional fees which are very small. Having entered their profession well equipped in knowledge, they should be held up to asepsis in the care of their materials, the cleansing of their hands, and that of the patient. It should be made for their interest to call in a physician when there is an abnormality of presentation or other dangerous conditions, instead of having to pocket their pride when they need the assistance of a physician. There would then be fewer bad cases of neglected labor in deformed pelves, of delayed labor from malpositions, and of sepsis following frequent examinations and hours of suffering, to attend to, and there would be fewer still-born infants.

As a matter of fact most of the serious cases brought into a maternity hospital during labor are those that have been attended by a well meaning but ignorant midwife, and in which complicated conditions have been allowed to proceed until delivery had become impossible without greater danger to the mother, and the necessity of sacrificing the life of the infant in many cases.

ANTITUBERCULOUS WORK AMONG THE NEGROES.

It is well known that the negro is especially prone to suffer from tuberculosis, the ratio of tuberculosis deaths to the general population being nearly four times larger in the colored race, especially those of mixed blood, than among the whites. The necessity, therefore, of caring for the tuberculous negro and of inculcating hygienic habits in the race is most apparent, yet there seems to have been little or nothing done in an organized way until recently. In the North, inspired by the example of their white neighbors and by the tuberculosis exhibits in the larger cities and at the county fairs, the educated negroes have done more or less in the way of inculcating sound hygienic doctrine among their people. For example, the observance of the "health month" last February, during which it was urged that the subject, "Tuberculosis Among the Negroes: What Are We Going to Do About It?" be discussed in every colored church, lodge, and society, did much to awaken interest in the question. In the

South the first Negro Congress on Tuberculosis was held at Tuskegee the third week in December of last year; at this meeting it was decided to establish permanent tuberculosis committees at Tuskegee, Hampton, Shaw, and other negro institutions, each to push the antituberculosis campaign in its own neighborhood by means of lectures, articles in the colored press, and the distribution of leaflets to be supplied by the State boards of health.

This most commendable movement has recently acquired a new impetus through the labors of Dr. Wertenbaker of the Public Health and Marine-Hospital Service. At the conclusion of a lecture on tuberculosis, which he gave in February last before a negro farmers' conference at Savannah, he suggested the organization of a State Antituberculosis League for Negroes, with a vice-president in each county whose duty it should be to organize a branch of the league in every negro church in his county. The suggestion was at once acted upon and the plan, as we learn from *Public Health Reports* for August 6, has met with general approval. The movement has spread from Georgia to the other Southern States, leagues having already been established in Georgia, Louisiana, Mississippi, North Carolina, and Virginia. Furthermore, at a recent meeting of the National Association of Colored Teachers at Asheville, N. C., a committee consisting of one representative from each of twelve States was appointed to urge the organization of such leagues in their respective States, and the prospects are that quite a number of States will soon be organized. The movement was also heartily endorsed by the latest conference of State and Territorial boards of health, the conference urging upon the members the desirability of promoting as far as possible its inauguration and success.

No argument is needed to prove the benefits which will follow upon arousing the enthusiasm of the negroes, especially in the South, in the war against tuberculosis. These benefits will be felt in equal if not greater degree by the whites, for as Wertenbaker says, any improvement in the health conditions among the negroes will also be beneficial to the white race. In the South, where the negroes are chiefly employed as cooks, nurses, house servants, etc., they are brought into intimate contact with the whites, and infection among the negro servants is liable to be communicated to the white members of the household. The Public Health and Marine-Hospital Service has, in the encouragement it has given to this movement, again justified its establishment as a national health organization, and no one can doubt the still greater good it will do when it is detached as a bureau from the Treasury Department and made an independent department of the national government.

Paralysis of the Tongue Following Staphylococcus Angina.

The appearance of paralysis of any form following closely upon a severe, or even a mild, attack of sore throat is usually considered as *prima facie* evidence of the action of the diphtheria bacillus, and not infrequently the diagnosis of diphtheria is made on these two symptoms alone even when, at the time of the examination, the inflammation of the throat has disappeared, and a culture fails to reveal the presence of the specific organism of the disease. Osler goes so far as to state that the appearance of paralytic symptoms after a supposed follicular tonsillitis indicates a diagnostic error. On the other hand it is known that one form or another of paralysis may occur as a more or less rare exception after practically every infectious disease, and though it is undoubtedly a decided rarity for it to occur after a simple tonsillitis, such a possibility should not be ignored. A peculiar form of postanginal paralysis is described in the *Deutsche medizinische Wochenschrift* for July 15, 1909, by Schlippe of Darmstadt. His patient, a young woman with a decided predisposition to angina attacks, was taken acutely ill with high fever, sore throat, extreme bilateral tonsillar swelling and exudate, difficulty in opening the mouth, marked lymphadenitis, and edema under the chin. Repeated cultures from the throat showed staphylococci but no diphtheria bacilli. After a few days, during the acute febrile attack, the patient noticed an inability to use the tongue properly and a definite paralysis of the left side of the organ was discovered. This remained after the patient's recovery, but gradually disappeared three months later. There was hemiatrophy of the tongue and the electrical examination showed the reactions of degeneration on the atrophied side. The hyoid branch of the hypoglossal nerve did not appear to be involved, and no other paralyses were to be found. Five similar cases are recorded in the literature, all of which, however, differed from the present case in that the paralytic symptoms appeared from two to four weeks after the acute illness. All recovered after periods varying from ten days to three years. The paralysis seemed to be entirely peripheral in type and to have involved only the lingual branch of the hypoglossal nerve. Whether it was toxic in origin or due to direct extension of the inflammation from the throat was difficult to determine.

Eruptions After Abdominal Operations.

Surgeons are very often made uneasy by the appearance of rashes in patients after abdominal operations. Such rashes immediately suggest the development of general sepsis or of a complicating disease such as scarlet fever, which, as is well known, often makes its appearance in connection with wounds. However, the patient is usually but little the worse for the rash, for the latter fades sooner or later while the healing of the wound goes on to its usual termination. It has therefore become quite the fashion to blame for the appearance of the rash the various coal-tar preparations so often administered to patients after operations. Writing in the *Journal of Cutaneous Diseases* for July, 1909, Francis J. Shepherd brings forward a great deal of convincing evidence against this explanation. When the coal-tar drugs were discontinued by him eruptions still appeared from time to time among patients who underwent various abdominal operations. It finally occurred to the writer that the enemata which are almost universally administered after operations might have something to do with the appearance of rashes, especially as turpentine was a frequent ingredient. However, the omission of this substance seemed to have no effect upon the frequency of eruptions. It was then noticed that usually yellow soap was used in making

up the soap and water mixture for the enemata, though occasionally castile soap was employed. The possible explanation of the eruptions then suggested itself when a patient developed a rash after an enema of soap-suds made of plain yellow soap but failed to show an eruption after a later enema made of castile soap. In view of this castile soap was generally used in making soap-suds for enemata and rashes then became much less frequent. Shepherd thinks that excess of resin present in the common soaps is probably responsible for the occurrence of these rashes. Of course, a certain percentage of the eruptions may be due to the anesthetic. Shepherd's observations can be so easily repeated in any large hospital, that there need be no difficulty in securing a corroboration or a disproval of his explanation.

News of the Week.

The New York Milk Committee reports that during the past year 1,773 infants have received milk from the seven depots under its care, of which 1,207 were regularly under the supervision of the committee's physicians and nurses.

Robbing Physicians.—Several physicians in New York City have been victimized lately. A well dressed young woman has been calling on physicians for advice and tendering checks for sums above the physician's fee in payment, thus receiving money in change, the checks later proving worthless. A well dressed young man, very slender, and of fair complexion has called at doctors' offices during their absence and collected sums of money on what purported to be instruments ordered by the doctors. The package has contained moth balls.

Licenses for Optometry.—Letters have been sent out in the past few days by the officers of the Optical Society of the State of New York to the branch societies in various cities, asking that action be taken to enforce the new optometry law and to prevent persons from practising optometry without a license. Accompanying the letters were copies of a legal opinion, prepared for the society by former Senator William W. Armstrong of Rochester, as to the most effective means of prosecuting violators of the law. The law becomes fully effective this month, and from now on no more certificates will be issued except to candidates who have had preparatory education equivalent to at least two years in high school and have taken a two years' course in one of the schools of optometry recognized by the Regents of this State.

Quarantine on Sheep.—The Department of Agriculture has announced a quarantine on sheep in Kentucky owing to an epidemic of scabies which prevails there.

The Fly Committee of the Georgia State Medical Association met recently at Atlanta and organized for the purpose of working in connection with the State Board of Health in making war on flies. A report, setting out the dangers of the spread of diseases by flies and giving a number of timely suggestions relative to the destruction of the pests, was adopted.

An Epidemic of Anterior Poliomyelitis is reported in Winona, Minn. Dr. H. W. Hill epidemiologist of the State Board of Health, has been investigating the epidemic.

The Medical Department of Carroll College, recently formed by a merger with the Wisconsin College of Physicians and Surgeons, has announced the appointment of Prof. Wilbur O. Carrier, *president,* and Dr. Thomas C. Phillips, *dean.*

The London Home of Recovery has received a donation of $500,000 from Mr. E. F. Schiff in memory of his brother, Mr. S. B. Schiff.

New Cancer Hospital for London.—The trustees of the fund left by Henry Barnato to found a hospital in memory of his brother, Barney Barnato, and his cousin, Woolf Joel, have decided to devote the sum, amounting to $1,250,000, to the building and endowing of an institution for cancer patients in London.

Hospital for the Criminal Insane.—The ceremony of the laying of the cornerstone of the new Pennsylvania State Asylum for the Criminal Insane was held at Fairview, Pa., on July 24, 1909. Dr. Charles G. Wagner, superintendent of the New York State Hospital at Binghamton, delivered the oration on the occasion.

New Hospital for Payson, Utah.—A new well equipped hospital to be known as the Payson Hospital was opened in Payson, Utah, recently. The physicians in charge are Dr. P. P. Musser of Salt Lake City and Dr. Tilson of Payson.

Application for Tuberculosis Hospital.—The Workmen's Circle, a national fraternal insurance organization, has applied to Health Commissioner Porter for permission to erect a sanatorium at Liberty, N. Y., for tuberculous patients among its members. The organization has 27,000 members, each one of whom will be assessed $1.10 a year toward the maintenance of the hospital. It is to accommodate forty patients.

Tuberculosis Camp Ordered Closed.—The new tuberculosis camp recently established in Orange, N. J., by the Antituberculosis League of the Oranges has been ordered discontinued by the Orange Common Council as a result of a series of complaints made by residents in the neighborhood of the camp, which is located in a prominent residence section of Orange. In the resolution adopted by the Council it is set forth that the Anti-Tuberculosis League had no legal right to open the camp without first obtaining the permission of the governing body, as provided for in the State health code.

New Sanatorium for the Tuberculous.—The Health Commissioner of Milwaukee, Dr. G. A. Bading, has received plans for a tuberculosis sanatorium, to be built in Wauwatosa. This building will be built on the top of a hill, will be two stories in height, and will have large porches on three sides to enable the patients to get the advantage of the sunshine and air.

The Metropolitan Insurance Sanatorium Refused.—The application of the Metropolitan Life Insurance Company to build a sanatorium for tuberculous policy holders has been refused by the State on the grounds that the insurance law enacted in 1849 forbids insurance companies owning real estate except such as is necessary for the transaction of their regular business.

The Provident Savings Life Assurance Society has created a Health Bureau, which aims to help policyholders by prevention of disease and discovering it in time to check or cure it. This will be done through the medium of health bulletins, correspondence, and free medical examination every two years of such policyholders as request it.

Hospitals for Hudson-Fulton Celebration.—Elaborate plans have been made for the medical care of the visitors who will attend the Hudson-Fulton celebration in New York in September. Rest stations, comfort stations, medical stations, registration bureaus, and information bureaus will be established in all parts of the city and particular attention will be paid to caring for the crowd who witness the land and naval parades. Already one-third of the churches have agreed to keep their edifices open as rest stations between the hours of 9 A.M. and 9 P.M., with nurses and other attendants on duty. For the entire time of the celebration a large number of emergency hospitals will be open and six army tents will be put up. Each tent and each emergency hospital will contain twelve cots and will have nurses, orderlies, and physicians on duty all hours of the day and night. Fifteen hundred trained nurses have already volunteered their services. In the three days of the land parades temporary emergency hospitals will be established every five blocks, with ambulances stationed every ten blocks, and special arrangements will be made with the public and private hospitals. At each of these temporary emergency stations physicians and nurses will be in attendance. For the two water events of the celebration similar arrangements will be made where the congestion will be greatest, and an innovation in the form of ambulance launches will be introduced with nurses and doctors in attendance.

Change in Address of the A. M. A.—Beginning September 1, the number of the American Medical Association Building will be 535 Dearborn avenue. This is in conformity with the new system of street numbers of Chicago.

Appointments.—Dr. James L. Greene, superintendent of the Kankakee Hospital for the Insane (Illinois) was recently appointed alienist member of the Board of Administration for the State Institutions. Dr. James A. Nowlen has succeeded Dr. Frank Fitzgerald as local surgeon of the Chicago and Northwestern Railroad Company at Morrison, Illinois, Dr. Fitzgerald having resigned. Dr. Harry C. Blankmeyer has been appointed pathologist, and Dr. Morris Altman obstetrician, on the staff of the Springfield (Illinois) Hospital. Dr. Shallenberger, Canton, Illinois, has been appointed local surgeon for the Chicago, Burlington, and Quincy and the Toledo, Peoria, and Western railroads. Dr. J. Rex Sholl has been appointed Health Commissioner of Peoria, vice Dr. Albert Weil, resigned. Dr. Stephen C. Glidden, Danville, chief surgeon of the Illinois Traction System Hospital Association, has resigned. Dr. R. T. Hinton has succeeded Dr. Elmer L. Crouch, resigned, on the staff of the Jacksonville Hospital for the Insane.

The International Dental Congress is to hold its session in Berlin, August 23-28. Special subjects for discussion will be school and military dental hygiene.

The Mississippi Valley Medical Association will hold its thirty-fifth annual meeting at the Southern Hotel in St. Louis, October 12 to 14, 1909. The president of the association is Dr. J. A. Witherspoon of Nashville, Tenn.; the secretary, Dr. Henry Enos Tuley of Louisville; the treasurer, Dr. S. C. Stanton of Chicago, and the chairman of the committee on arrangements, Dr. Louis H. Behrens of St. Louis. The oration on Medicine will be delivered by Dr. Sherman G. Bonney of Denver, and that on Surgery by Dr. John B. Deaver of Philadelphia. A joint session will be held to discuss the subject of exophthalmic goiter.

The Second International Food Congress will be held in Paris, October 17 to 24, 1909. The purpose of the congress is the repression of adulteration in food, chemical products, drugs, essential oils, aromatic substances, mineral waters; etc. Professor Bordas is the president, M. Ch. Franche, 16 Place Vendome, Paris, general secretary, and M. Maurice Riviere, 16 Place Vendome, Paris, treasurer. The work of the congress will be divided into three sections. The first section, on alimentary technology, is under the presidency of Professor Muntz. The second section is on hygiene, with Dr. Landouzy as president. The third section is on crude drugs, essential oils and crude aromatic substances, chemical products, and mineral waters, with M. Guignard as president. The congress is to be held under the auspices of the Society of the White Cross of Geneva. The first international food congress was held in Geneva in 1908, and considered definitions of food and alimentary substances. The third will be held in 1910 at The Hague and will take up chemistry and hygiene, and the fourth, in London in 1911, the subject of legislation in connection with food and alimentary substances. The membership is divided into three classes: donor members, fee $20, who will participate in the proceedings, receive the publications, and have their names at the head of the list of members; titulary members, fee $4, who also participate in the congress and receive publications; and associate members, fee $2, members of the families of the other members, who may attend the meetings but do not participate. Subscriptions should be sent to the treasurer.

The Oregon, Washington, and Idaho State Medical Association, meeting in joint session in Seattle, Washington, on July 23, elected the following officers: WASHINGTON—*President*, Dr. W. Kirkpatrick of Bellingham; *Vice-Presidents*, Dr. J. M. Semple of Medical Lake and Dr. W. M. Beach of Shelton; *Secretary*, Dr. C. H. Thompson of Seattle; *Treasurer*, Dr L. L. Lover of Tacoma. OREGON—*President*, Dr. E. A. Pierce of Portland; *Vice-Presidents*, Dr. R. G. McDaniel of Baker City and Dr. J. M. Ferris of Corvallis; *Secretary*, Dr. William House of Portland; *Treasurer*, Dr. Edna Timms of Portland. IDAHO—*President*, Dr. J. L. Stewart of Boise; *Vice-President*, Dr. G. H. Coulthard of Idaho Falls; *Secretary-Treasurer*, Dr. E. E. Maxey of Idaho Falls.

The Lamoille County (Vt.) Medical Association, at it annnal meeting held at Burlington on July 28, elected the following officers for the ensuing year: *President*, Dr. George L. Bates of Morrisville; *Vice-President*, Dr. H. W. Barrows of Stowe; *Secretary and Treasurer*, Dr. W. M. Johnstone of Morrisville: *Censors*, Dr. W. M. Johnstone, Dr. J. C. Morgan of Stowe and Dr. J. H Newton of Cambridge; *Auditor*, Dr. George L. Bates; *Delegate to State Convention*, Dr. A. J. Valleau of Morrisville.

Obituary Notes.—DR. WILLIAM C. DOANE of Elmira, N. Y., died August 2, aged 83 years. He was a graduate of the University of Vermont in 1846. Dr. Doane was one of the committee which wrote the first platform of the Republican party. He was inspector of prisons under General Grant.

DR. GEORGE HEYWOOD of New York died on

July 30, 1909, aged 47 years. Dr. Heywood was a graduate of Harvard College in 1883 and received his medical degree from the Harvard Medical School in 1887. He was a member of the New York County Medical Society, the Medical Association of Greater New York and the New York State Medical Association.

Dr. George D. Dowkontt of New York died in Brooklyn July 31, 1909, aged 66 years. He was a graduate of the Jefferson Medical College in 1881. Dr. Dowkontt was the founder of the International Medical Missionary Society.

Dr. James Stafford of Perth Amboy, N. J., died at his home August 3, 1909, aged 48 years. He was a graduate of the University of Vermont in 1885. He was an assistant surgeon in Cuba in 1898, with the rank of captain, and was afterward made a brevet major for his services in stamping out yellow fever in Cienfuegos and Santiago.

Dr. R. A. M. Collins of Gilbert, Iowa, was shot and killed on July 24, 1909, at his home. Dr. Collins was a graduate of the Drake University School of Medicine in 1904.

Dr. C. F. Warner of Mankato, Minn., died at his home on July 25, aged 77 years. He was a graduate of the Jefferson Medical School in 1854, and was local health officer for many years, alderman, and president of the council in his home town.

Dr. Augustus Lewis of Greenville, Ky., died on July 27, 1909, aged 70 years. He was a graduate of the University of Tennessee in 1879, and a member of the Muhlenberg County Medical Society and the Kentucky State Medical Society.

PROFESSOR LUDWIG BRIEGER.

The death of Ludwig Brieger removes from the faculty of the Berlin University its most versatile member. Although Brieger had reached his sixtieth year only, the record of his manifold achievements presents a monument of a laborious life and of tireless devotion to science. He was assistant in Quincke's Clinic at Bern from 1877 to 1878 and in Frerichs' Berlin Clinic for seven years. Here he received the titular professorship together with his friend and colaborer Ehrlich. He labored in Leyden's clinic two years, during which time he was director of a separate polyclinic of 2,000 cases. When the epoch-making labors of Robert Koch induced the faculty to establish a special clinic for infectious diseases Brieger was chosen his chief assistant. In 1901 he was appointed Professor of General Therapeutics with special directions to teach hydrotherapy. In order to obtain a practical insight into this branch of therapeutics Brieger (as he personally informed the writer) made a tour of observation to the fountain head—Professor Winternitz of Vienna—and to other institutions. To the great esteem in which he was held by Minister of Education Althof was due the construction of a splendid hydrotherapeutic institute under Brieger's direction. This special clinic became so popular with students and patients that in three years it became necessary to enlarge it greatly. The writer has met German, Austrian, Russian, Japanese, and Swiss students at this clinic, which is not only a large outdoor one but also has a division in the Charité. That so renowned a man was willing to nurture this neglected child of medicine does honor to him and demonstrates that suffering humanity had in Brieger a sympathetic investigator. He has contributed much scientific and practical work to hydrotherapy.

Brieger was a patient and courageous investigator of ptomain and arrow poisons and received the pseudonym Pfeilgift (Arrowpoison) Brieger. During a visit to the hydrotherapeutic clinic of Brieger last year the professor conducted the writer with much pride through its various branches—consisting of an animal house for subjects of immunity experiments, a laboratory for extracting essential oils, perfumes, gums, and various nutritious elements of African nuts for the colonial department of the German empire, also an ingenious apparatus for obtaining the poisons from living venomous snakes, which department Doctor Krause managed with an enthusiasm that was contagious. In another department the writer saw a large number of arrows used by the African savages, many of them with sad histories. Some remarkable results of cataphoric currents on goiter and other tumors were observed in the well-equipped electrical division, and in another the professor displayed his recent trypsin experiments on cancer, which are now familiar to the profession. Those who know Brieger only as the patient and successful bacteriologist who has given us a deeper insight into the principles of immunity, of ptomains, toxins, and other intricate laboratory subjects wonder that he had devoted his last and most useful years to hydrotherapy—a branch which until recent years has received but scant attention in the schools. Brieger's brilliant achievements and his earnest advocacy of hydrotherapy have doubtless added greatly to its prestige.

As an evidence of the high esteem in which Brieger was held it may be mentioned that when the splendid German Society for People's Baths, which contains in its directorate members of the aristocracy, of the army, navy, and others of renown, lost its brilliant originator and president, the lamented Lassar, Brieger was elected successor to the latter, and after Liebreich's death he was elected president of the German Balneological Society, also. So eminently a useful life cannot but serve as an example to the rising generation of physicians.

Simon Baruch, M.D.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

A WEEK OF CONGRESSES—KING'S COLLEGE HOSPITAL—ORTHOPEDIC HOSPITAL—INVESTITURE BY THE KING.

London, July 23, 1909.

A Health Congress, organized by the city and University of Leeds, with the cooperation of the Royal Sanitary Institute and the Royal Institute of Public Health, has been sitting all the week at Leeds. Above eleven hundred delegates of the many branches of medical and sanitary science attended. The president, Col. T. W. Harding, in an opening address, said that in science, as in industrial production, division of labor had become a necessity, but there was some danger that the specific worker in a limited field might lose sight of wider issues. There was much to be learned still of bacteriology, but we know now that of the myriads of microorganisms the vast majority are beneficent and life on the earth would not be possible without them. While appreciating the progress of sanitary science, he doubted whether we were on the whole healthier than our fathers, whose lives were more rational; e.g. in the old conditions 75 per cent of the population was rural, now 77 per cent. was urban.

Still phthisis was being controlled, though the deaths

were still terribly numerous. In 1907 they amounted to 42,000 in England and Wales. Still the mortality was not much over a third of what it was in 1851. For 100 deaths in 1869 there were now only 46. The birth rate had declined since 1880, the causes being obscure. He warmly commended physical exercises and games in schools and later military drill and discipline to improve the race.

On Monday the most popular section was devoted to the bringing up of children. Over this Sir J. Crichton Browne presided and reiterated views he had always held, especially urging that nutrition should come before education, and that millions of money were squandered by putting instruction into bodies unfit to receive it.

One speaker demanded artistic school surroundings. Several strongly advocated open-air schools. Dr. Marsden said one always heard sentimental rubbish when practical questions were under consideration. Artistic schools were very well for rich people, but economy lay in plainly constructed buildings and saving the ratepayers' pockets. It was lamentable to see children in a filthy and even verminous condition being taught Tennyson and Shakespeare instead of how to keep themselves clean. Dr. W. Hall admired the open-air system, but objected to children's heads and feet being exposed to cold. Sir C. Cameron said in Ireland, with about 200 rainy days a year, open-air schools seemed undesirable, and regretted that medical inspection was not yet extended to Irish schools.

The university conferred honorary degrees in the afternoon—LL.D. on Col. T. W. Harding, president; D.Sc. on Sir J. Crichton Browne and on Major Ronald Ross.

On Tuesday prevention of disease was the subject to the fore and attracted a large audience. Dr. Arthur Newsholme read a paper on "Some Conditions of Social Efficiency," in which he maintained that the whole range of physical, mental, and to a large extent moral life of mankind might be brought within the range of preventive medicine. The sanitary authority which spent money lavishly on an isolation hospital but neglected to search out by bacteriological and clinical investigations the "missed cases" which continued to spread infection was comparable to a specialist who busied himself with a nasal polyp in a patient who was dying of consumption. If sanitary authorities realized the loss of life from communicable diseases they would be less likely to build extravagant town halls while the essentials of public health were unattended to. The Poor Law Commission showed that much of the three to four millions a year spent on outdoor relief was a subsidy to unsanitary, disorderly, or even vicious habits of life. Repeated attacks of delirium tremens were treated without any effort to compel the sobriety of these patients after the first attack, even though it might be necessary to prevent them handling their own wages. So the children of the soaker were fed and clothed, with no diversion of wages other than an occasional fine for drunkenness. Extravagant parsimony characterized our dealing with tuberculosis, though combined effort to reduce its prevalence was the best investment a community could make.

A discussion on tuberculosis was opened by Dr. Robertson, Medical Officer of Health for Birmingham, who supported the views of Dr. Newsholme and argued for the encouragement by every means of the improvement of the conditions of living.

On Wednesday Dr. G. Newman addressed a large general meeting in the University Examination Hall on child mortality. He held that future measures of preventive medicine must start from the child and deal more with the home than the house. Not that the State should invade the home and discharge the individual's responsibility, but should teach him, particularly the parent, that his responsibility had increased. The true foundation of physical improvement must be laid deeply and broadly in childhood.

In the sections Dr. Herbert Williams, Medical Officer of the Port of London, dealt with the protection of food supply and desired the assistance of sanitary inspectors to look after imported foods. He was supported by Dr. Dearden, the Manchester Port Officer, who dealt specially with canned foods, who did not think there was much danger in them, but considered the Local Government Board should have power to prohibit those dosed with preservatives or with copper, as well as certain brands of condensed milk.

Yesterday the most popular papers dealt with the health of women wage earners. Miss E. H. Jones, Chief Sanitary Inspector at Bradford, said in that town 22,000 single and nearly 6,000 married women worked at wool-combing, an industry very injurious to health. If hygienic conditions were good, she doubted whether work in married women affected infant mortality, and forbidding it might lead to worse evils, for increased wages meant more home comforts. But the system fostered selfishness, men often choosing wives for their earning capacity. In no class were drunkenness and vice so common as among woolcombers.

Miss Carey, Chief Lady Sanitary Inspector, Westminster, said the only labor from which nature indicated that women should be debarred was such as demanded great physical energy. She was glad to see increasing interest and sympathy among employers toward their women workers.

Other questions occupying the congress this day were lead poisoning in earthenware factories, tuberculosis in cows, and the training of children.

Another congress has also been sitting all the week. That is the twelfth International Congress on Alcoholism, opened on Monday by the Duke of Connaught. About 1,000 delegates attended, 400 from foreign countries. In the afternoon the Dean of Hereford opened an exhibition illustrative of every phase of the temperance question, arranged in stalls at the Imperial Institute, where in the evening the First Commissioner of Works received the officials and members on behalf of the Government.

Tuesday was largely concerned with the education of school children and students and further to the education of the teachers themselves, on which last interesting papers were read by MM. Petersen of Kiel and Ambert of Paris. After this many members visited the Temperance Hospital, where Dr. Holitsher of Karlsbad presented a report on the treatment of pneumonia and typhoid with and without alcohol. From statistics he had collected from 47 hospitals, out of 238 cases of pneumonia treated with alcohol the death rate was 24.3; of 248 without any, 21.3 per cent. Of 48 cases complicated by delirium tremens alcohol was given in 21 and the deaths were 15, while of the 26 in which it was not given only 9 died. On account of the small number of cases reported, he did not pretend that the difference between 24.3 and 21.3 was a solution of the question about the effects of alcohol, but it certainly proved that alcohol did not cure pneumonia. It was clear, too, that in intricate cases alcohol should not be given. Of typhoid, 161 cases from eight hospitals were considered. Of these, 80 had alcohol and 15 of them died; 81 had none and 12 died. The statistics again did not quite settle the question. If 20,000 cases were reported on showing a lower mortality without alcohol it would be more conclusive.

In the evening the third Norman Kerr lecture was delivered by Prof. Taav Laitinen of Helsingfors, who gave in it the results of three years' experiments he had carried on with a view of ascertaining whether the resistance of the red blood corpuscles against normal or an immune serum is diminished by the use of alcohol. From investigation on 228 persons he found that it is so diminished. The normal hemolytic power of human serum is less in consumers of alcohol than in abstainers. So is the precipitating reaction between human blood serum and immune serum from animals obtained by immunizing them with human serum. Furthermore, the experiments showed that the bactericidal power of the blood against typhoid bacteria was less in drinkers than in abstainers. Altogether, then, it appears that the effect of moderate quantities of alcohol injures the protective mechanism of the body.

On Wednesday the discussion was again largely concerned with children and a number of papers were submitted. I can only mention the more strictly medical, preferring those of foreign visitors. Dr. Imri Doezi, representing the Hungarian Government, read one on the effects of alcohol on the child, in which he related how wide was its distribution as shown by statistics. In some parts cheap brandy was given them regularly at breakfast and in those communities the birth rate was steadily falling. Occasionally a child came to school intoxicated. The effect on children was to make them nervous, inattentive, melancholy, and sometimes immoral.

Dr. Hercod of Lausanne read a paper on the legal protection of children against alcohol, in which he suggested serious legislation against unworthy parents. In the discussion on this it was stated that in this

country 12,500 widows were made by alcohol every year.

Prof. Taav Laitinen discussed the influence of drink on the degeneration of human offspring, and the professor gave a report on the consumption of alcohol in hospitals and asylums, showing that in those institutions in Germany, Austria, and Switzerland there had been a great diminution during the last twelve years, and the decrease, he thought, would continue.

Dr. Legrain of Paris read a paper on inebriety and insanity, in which he declared that society was full of people soaked to the very marrow with alcohol, which ought to be prohibited as a poison, like phosphorus, etc.

The Lord Chief Justice presided in the evening at a demonstration of the national services—sailors, soldiers, postmen, and railway men. His Lordship said that after forty years at the bar and ten years' experience as a judge he knew as a fact that 90 per cent. of the crime of the country depended on intemperance.

Yesterday the economic effects of the production and consumption of alcohol and vital statistics connected therewith occupied the congress and after the debates a garden party at Henley.

To-day the effects on the brain and nervous system and also a special meeting for ladies only.

To-morrow crime and alcoholism in reference to legislation will be discussed and a farewell dejeuner given to the foreign guests.

Nurses have also held an International Congress this week, and to-morrow the delegates are to visit Windsor Castle. The question of State registration has occupied them a good deal and they seem to think it would do much to secure them a professional position and protection. If they knew how little the General Medical Council has done for doctors they would be less hopeful of such assistance.

At one session an address was given on the relations of nursing to medicine, in which the lady presiding said there was danger lest the nurse's admiration for medical skill and interest in science should lead her to feel some contempt for the humbler duties on which the comfort of the patient so much depended. Once the idea of making the patient comfortable was lost sight of, much of the charm of nursing would be lost.

Yesterday the morning meeting was occupied with the nursing of the insane. Dr. Robert Jones of the Claybury Asylum and lecturer at St. Bartholomew's Hospital on mental disesaes, read the principal paper, in which he pointed out the difference between our time and one hundred years ago. He thought the example of Florence Nightingale was the mainspring of the improved nursing of the insane. He held that all great public asylums ought also to be training schools for nurses. He feared the official view was otherwise, lest it should lead their trained nurses to leave for better situations. Even if so, the training asylum systematically maintained the best service and the nurses took a more enlightened interest in their work. Miss Parsons of the Shepperd and Enoch Pratt Hospital, Baltimore, followed and argued that some hospitals advertised no bars and no restraint, but that was going too far, like most reforms, and might lead to an opposite movement.

At the afternoon meeting the Secretary for War gave an address on the "Nurse as a Patriot." He was continually interrupted by suffragettes, although he is in favor of votes for women.

The members of the congress were received by the Lord Mayor and Lady Mayoress at the Mansion House.

The King, accompanied by the Queen and Princess Victoria, went in semi-state to Denmark Hill and laid the foundation stone of the new building to which King's College Hospital is to be transferred on its completion. In replying to an address, His Majesty spoke of an interest he always felt in the hospital and approved its removal to a more necessitous district. He alluded to the association of the hospital with the great work of Lord Lister, which had "rendered an inestimable benefit to England and to all mankind." He remembered, too, that the hospital had sent out some of the most distinguished of its staff to do their generous work in the South African War.

Yesterday His Majesty held an investiture, when numerous orders and decorations were conferred, among them Col. D. Wardrop, Commandant of the Royal Army College, and Surgeon-General Whitehead, P.M.O., the Victorian Order. Prof. William Simpson, for his plague services, received C.M.G. Lieutenant Colonel William Leishman was knighted for his researches in bacteriology.

This afternoon the King, accompanied by the Queen, went in semi-state and opened the new buildings of the Royal National Orthopedic Hospital.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 29, 1909.

The Histological Classification of Tumors.—F. B. Mallory describes a limited number of characteristic cells and some of the varieties of tumors composed of them he demonstrates photomicrographically. The ordinary connective tissue cell or fibroblast is an elongated, flattened cell with a flat, oval nucleus, and is characterized by the production of two kinds of fibrilis, fibroglia and collagen Cells of this type produce a series of tumors ranging from the dense fibroma to the soft, rapidly growing fibrosarcoma. The myxoma and myxosarcoma differ from the tumors of this group in having a certain amount of fluid between the collagen fibrils. They should not, therefore be classed as a separate type of tumor. The smooth muscle cell is a long spindle-shaped cell with a rod-shaped nucleus, and is characterized by a number of fine striations running longitudinally in the cuticle of the cytoplasm. Slowly and rapidly growing tumors composed of the type of cell occur most commonly in the uterus, but may arise in other parts of the body. The neuroglia cell varies in shape and size and is characterized by the production of fibrils of one kind only, the neuroglia fibrils, which run parallel with the spindle-shaped cell and in all directions around the spherical cells. From this type of cell a variety of glioma arise. The endothelial cell is characterized by no production of fibrils, and gives rise to two types of tumors, the hemangioendothelioma and the lymphangioendothelioma. The first type occurs in two varieties, the capillary and the cavernous. Epithelial cells occur in great variety; so also do the epithelial tumors of which the cells tend to differentiate like the normal cells. Only the names of a few are mentioned. The vague terms, "spindle and round-cell sarcoma" and "peripheral angiosarcoma," should be avoided so far as possible. A spindle-cell sarcoma may be composed of connective tissue, smooth muscle, endothelial, or neuroglia cells. A round cell sarcoma may in reality be a lymphoma, osteosarcoma, malignant leiomyoma or neuroma A true perithelial angiosarcoma does not occur.

Injections of Sea Water in Skin Diseases.—In order to determine the possible therapeutic power of sea water, Charles J. White undertook some experiments. The sea water was obtained from the ocean about 30 miles south of Woods Hole, Massachusetts, and from a depth of 30 feet, thus insuring a pure, uncontaminated supply This water was brought to Boston and purified by passing through a filter and rendered isotonic with blood serum. The injections were made three times a week deep into the buttocks of the patient, who lay on his side and allowed the fluid to run into the tissues by the force of gravity. From a study of 15 cases treated by the injections of isotonic sea water, certain conclusions may be drawn: (1) This unusual therapeutic measure produces a certain amelioration of symptoms in widely various dermatoses. (2) This improved condition is most conspicuous in tuberculous processes, especially in tuberculous ulcers. (3) As a whole, this therapeutic agent is a great disappointment. (4) Sea water can be injected in surprisingly large amounts, even into children, without causing much pain or other untoward symptoms. (5) Sea water injected into the buttocks causes immediate desire to micturate, a contained easy and sometimes increased number of daily movements of the bowels, as a rule a slight tendency toward increase of bodily weight, and at times a distinct improvements in the well-being of the recipient.

Isolation of the Bacillus of Typhoid Fever from the Breast Milk of a Woman Ill with the Disease.—Charles H. Lawrence reports such a case. The patient was 23 years old and three months before entrance to the hospital she had been confined and was nursing her baby when she was taken sick with typhoid fever. The patient's milk contained typhoid bacilli. The possibility of contamination is very slight, for special precautions were taken to prevent such an occurrence. The patient's baby has shown no signs of illness. The positive Widal reaction obtained with the serum of infants who have been nursed by mothers ill with typhoid fever may explain the failure of the child to contract the disease in the majority of cases It seems equally possible, however, that in a few

cases the protective reaction in the child may be strong enough to resist the infection.

New York Medical Journal, July 31, 1909.
